## Symbols and Abbreviations

The following symbols and abbreviations, and others approved for the Système International d'Unités (SI), are used without definition in the following reports by the Divisions of Sport Fish and of Commercial Fisheries: Fishery Manuscripts, Fishery Data Series Reports, Fishery Management Reports, and Special Publications. All others, including deviations from definitions listed below, are noted in the text at first mention, as well as in the titles or footnotes of tables, and in figure or figure captions.

---

The Division of Sport Fish Fishery Data Series was established in 1987 for the publication of technically oriented results for a single project or group of closely related projects. Since 2004, the Division of Commercial Fisheries has also used the Fishery Data Series. Fishery Data Series reports are intended for fishery and other technical professionals. Fishery Data Series reports are available through the Alaska State Library and on the Internet: <http://www.sf.adfg.state.ak.us/statewide/divreports/html/intersearch.cfm> This publication has undergone editorial and peer review.

## ABSTRACT

Chinook salmon *Oncorhynchus tshawytscha* abundance in the Kenai River in 2004 was estimated using side-looking split-beam sonar technology. Early (16 May-30 June) and late (1 July-10 August) runs of Kenai River Chinook salmon have been monitored acoustically since 1987. A 200 kHz split-beam sonar system has been used since 1995 to estimate numbers of adult Chinook salmon migrating into the Kenai River. From 1987 to 1994, a 420 kHz dual-beam sonar was used to generate similar estimates. In 2004, the sonar project operated 16 May through 5 August. The total estimated upstream Chinook salmon passage in 2004 was 67,873 (SE = 641) fish: 15,498 (SE = 261) fish during the early run and 52,375 (SE = 585) fish during the late run. Total late-run passage estimate extrapolated through 10 August was 56,205 (SE = 1,784) fish. The standard errors associated with these estimates reflect only sampling error and not other sources of uncertainty including target detection, species composition, direction of travel, and target tracking. The early-run peak daily passage occurred on 10 June, with 50% of the run having passed by 14 June. The late-run peak daily passage occurred on 16 July, with 50% of the late run having passed by 18 July.

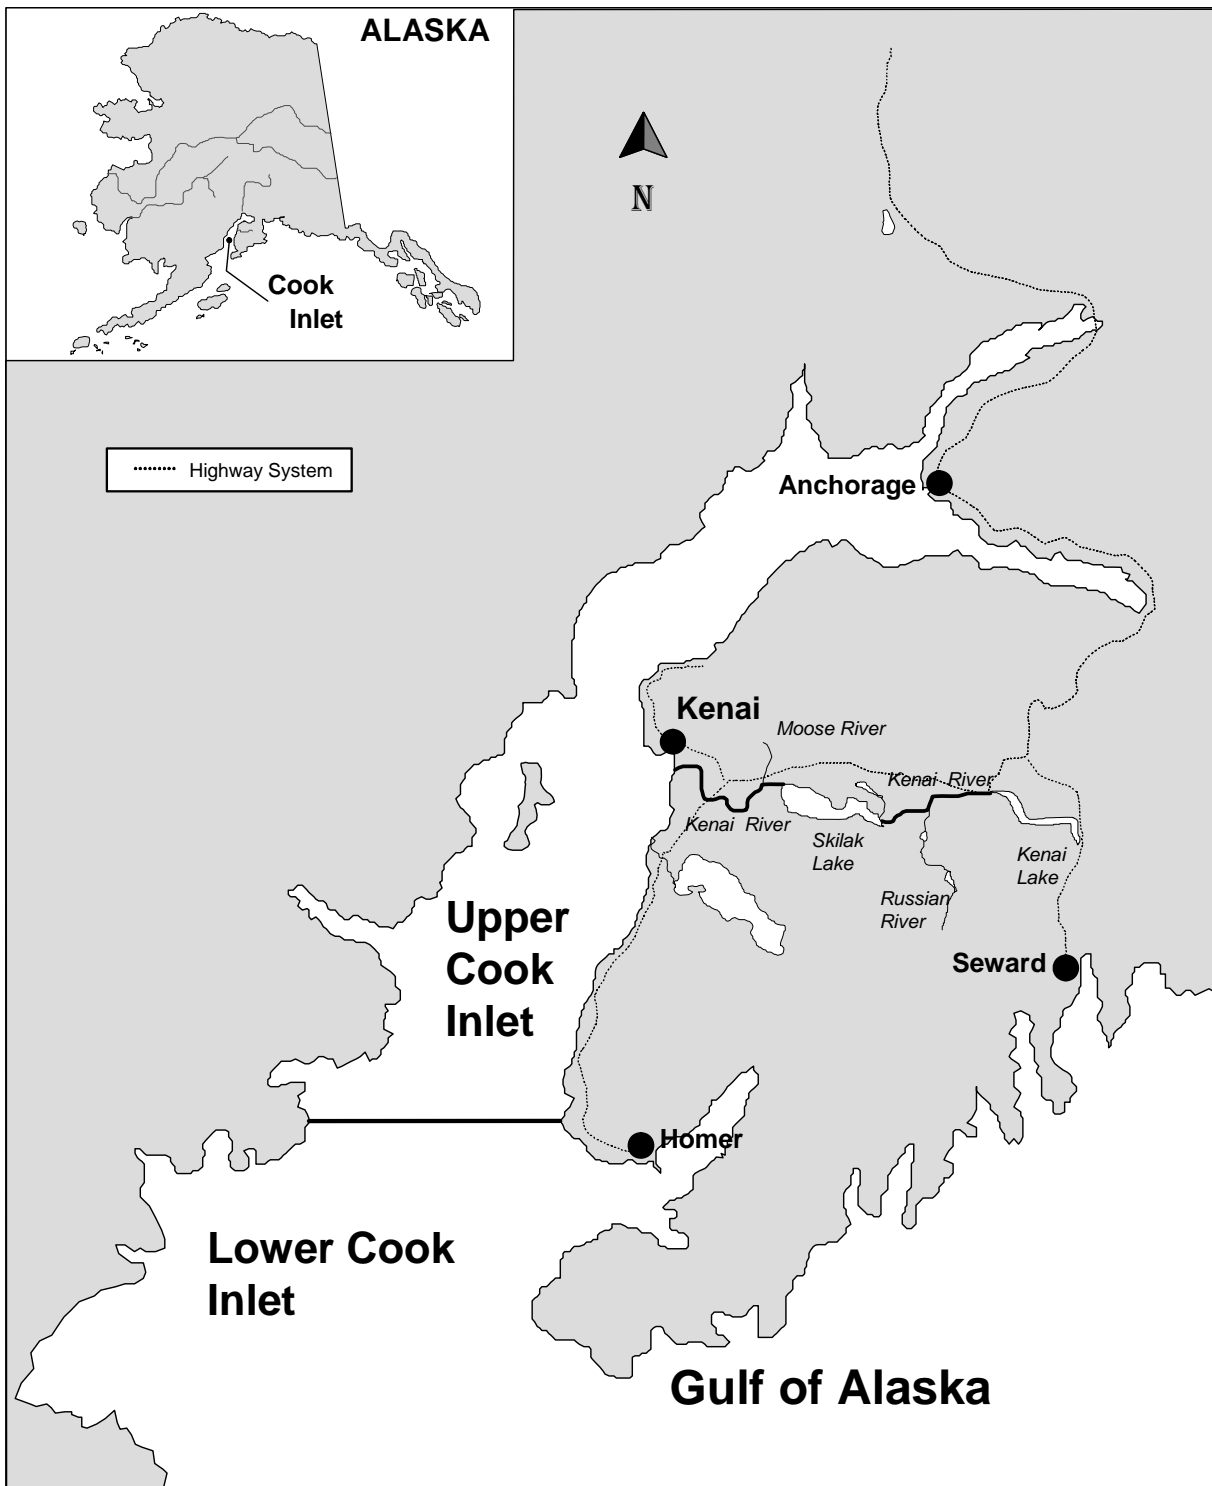

Key words: split-beam sonar, dual-beam sonar, Chinook salmon, *Oncorhynchus tshawytscha*, acoustic assessment, Kenai River, riverine sonar, early run, late run.

## INTRODUCTION

Chinook salmon *Oncorhynchus tshawytscha* returning to the Kenai River (Figure 1) support one of the largest and most intensively managed recreational fisheries in Alaska (Nelson et al. 1999). Kenai River Chinook salmon are among the largest in the world and have sustained in excess of 100,000 angler-days of fishing effort annually (Howe et al. 1995, 1996, 2001 a-d; Jennings et al. 2004, 2006a; 2006b; Mills 1979-1980, 1981a-b, 1982-1994; Walker et al. 2003). The Kenai River Chinook salmon fishery has been a source of contention because of competition for a fully allocated resource among sport, commercial, subsistence, and personal use fisheries.

Chinook salmon returning to the Kenai River are managed as two distinct runs (Burger et al. 1985), early (16 May-30 June) and late (1 July-10 August). Early-run Chinook are harvested primarily by sport anglers; late-run Chinook by commercial, sport, subsistence, and personal use fisheries. These fisheries may be restricted if the projected run size falls below escapement goals adopted by the Alaska Board of Fisheries. From 1989 to 1998 these runs were managed for spawning escapement goals of 9,000 early-run and 22,300 late-run Chinook salmon (McBride et al. 1989). In February 1999, the Alaska Board of Fisheries adopted new escapement goals based in part on Chinook salmon passage estimated by sonar and our best understanding of biases associated with the sonar (Bosch and Burwen 1999; Burwen et al. 1998; Hammarstrom and Hasbrouck 1998, 1999). The revised escapement goals define a range of escapement levels desired: 7,200 to 14,400 for early-run Chinook salmon (as defined by 5 AAC 56.070, Kenai River and Kasilof River Early-Run King Salmon Conservation Management Plan) and 17,800 to 35,700 for late-run Chinook salmon (5 AAC 21.359, Kenai River Late-Run King Salmon Management Plan). By providing flexible management it is anticipated that these escapement goal ranges will provide a stable fishing season without compromising either run.

Sonar estimates of inriver passage provide the basis for estimating spawning escapement and implementing management plans that regulate harvest in competing sport and commercial fisheries for this stock. Implementation of these management plans has been contentious and attracts public scrutiny. Restrictions on the sport fishery were imposed in each year from 1989 to 1992 to ensure spawning escapement goals were met. Since 1993, the 1997, 1998, 2000 and

**Figure 1.**-Cook Inlet showing location of the Kenai River.

2002 early runs, and the 1998 late run required a restriction of the sport fishery to meet escapement goals.

The first estimates of Chinook salmon abundance were generated for the 1984 late run with a mark-recapture project using drift gillnets (Hammarstrom et al. 1985). The mark-recapture project produced estimates of riverine abundance through 1990 (Alexandersdottir and Marsh 1990; Carlon and Alexandersdottir 1989; Conrad 1988; Conrad and Larson 1987; Hammarstrom and Larson 1986). These estimates had low precision and appeared to be biased high, particularly during the late run (Bernard and Hansen 1992).

To obtain timely and accurate estimates of Chinook salmon passage, the Alaska Department of Fish and Game initiated studies to determine whether an acoustic assessment program could be developed to provide daily estimates of Chinook salmon in the Kenai River (Eggers et al. 1995). Acoustic assessment of Chinook salmon in the Kenai River is complicated by the presence of more abundant sockeye salmon *O. nerka*, which migrate concurrently with Chinook salmon. From 1987 to 2003, sockeye salmon escapement estimates generated by the river mile-19 sockeye sonar project ranged from 625,000 to 1,600,000 (Westerman and Willette 2003) while late-run Chinook salmon escapement estimates generated by the Chinook sonar project ranged from 29,000 to 55,000. Dual-beam sonar was initially chosen for the Chinook sonar project because of its ability to estimate acoustic size (target strength), which was to serve as the discriminatory variable to systematically identify and count only Chinook salmon. Because of the considerable size difference between Chinook salmon and other species of fish in the Kenai River, it was postulated that dual-beam sonar could be used to distinguish Chinook salmon from smaller fish (primarily sockeye) and estimate their numbers returning to the river.

Early studies indicated that Chinook salmon could be distinguished from sockeye salmon based on target strength and spatial separation in the river. Sockeye salmon migrate primarily near the bank and were believed to have smaller target strengths than Chinook salmon, which primarily migrate near the midchannel area of the river. A target strength threshold was established to censor “counts” based on acoustic size. A range threshold was also used when sockeye salmon were abundant, that is, targets within a designated distance from the transducer were interpreted to be sockeye salmon and not counted. These two criteria have been the basis for discriminating between species and estimating the number of Chinook salmon returning to the Kenai River.

Daily and seasonal acoustic estimates of Chinook salmon have been generated since 1987. Estimates of total passage made with sonar were consistently lower than the mark-recapture estimates for the years 1987 through 1990 (Eggers et al. 1995). The inconsistencies between sonar and mark-recapture estimates were highest during the late run, presumably because of the mark-recapture biases mentioned above.

A more advanced acoustic technology known as split-beam sonar was used to test assumptions and design parameters of the dual-beam configuration in 1994 (Burwen et al. 1995). The split-beam system provided advantages over the dual-beam system in its ability to determine the 3-dimensional position of an acoustic target in the sonar beam. Consequently, the direction of travel for each target and the spatial distribution (three-dimensional) of fish in the acoustic beam could be determined for the first time. The split-beam system operated at a lower frequency that provided a higher (improved) signal-to-noise ratio (SNR; MacLennan and Simmons 1992). It also interfaced with improved fish-tracking software, which reduced the interference from boat wake, and improved fish-tracking capabilities (Burwen and Bosch 1996). The split-beam system

was deployed side-by-side and run concurrently with the dual-beam for much of the 1994 season (Burwen et al. 1995). Both systems performed similarly, detecting comparable numbers of fish. The split-beam data confirmed earlier studies showing that fish in general were strongly oriented to the river bottom. However, experiments conducted with the split-beam system could not confirm the validity of discriminating Chinook salmon from sockeye salmon based on acoustic size. These results supported modeling exercises performed by Eggers (1994) that also questioned the feasibility of discriminating between Chinook and sockeye salmon using target strength. It was hypothesized that discrimination between the two species was primarily accomplished using range thresholds on the acoustic data that exploited the spatial segregation of the species (sockeye salmon migrating near shore and Chinook salmon migrating mid-river; (Burwen et al. 1995; Eggers et al. 1995). In 1995, the dual-beam system was replaced with the split-beam system to take advantage of the additional information on direction of travel and spatial position of targets.

Two ancillary studies (Burwen et al. 1998) conducted in 1995 were directed at providing more definitive answers to remaining questions regarding: (1) the degree to which sockeye and Chinook salmon are spatially separated at the river mile-8.5 site; and (2) the utility of using target strength and/or other acoustic parameters as discriminatory variables for species separation. These studies confirmed the potential for misclassifying sockeye salmon as Chinook salmon. The netting study found that sockeye salmon were present in the middle insonified portion of the river, and in a concurrent tethered, live-fish experiment, most sockeye salmon tethered in front of the split-beam sonar had mean target strengths exceeding the target strength threshold.

Radiotelemetry projects were implemented in 1996 and 1997 to estimate the magnitude of bias introduced during periods of high sockeye passage (Hammarstrom and Hasbrouck 1998, 1999). These studies were designed to provide an independent and accurate estimate of inriver Chinook salmon abundance during the late run when the potential to misclassify sockeye salmon is greatest. Although the precision was similar, the use of radiotelemetry avoided certain biases introduced in previous mark-recapture estimates. Sonar estimates of late-run Chinook abundance were 26% greater in 1996 and 28% greater in 1997 than the telemetry estimates.

The inriver drift gillnetting project, originally designed to collect age sex, and length (ASL) samples (Marsh 2000), was modified in 1998 to produce standardized estimates of Chinook catch per unit effort (CPUE) for use as an alternative index of Chinook salmon abundance (Reimer et al. 2002). A drift zone was established just downstream from the sonar site and crews fished relative to the tide cycles. In addition, the schedule was intensified so that CPUE estimates could be generated daily. During subsequent years, inriver gillnet CPUE was used as a comparison with sonar passage estimates to detect periods when Chinook passage estimates were potentially high due to inclusion of sockeye (or other species; Bosch and Burwen 2000, Miller et al. 2002, Miller and Burwen 2002, Miller et al. 2003, 2004, 2005).

Analysis of the 1998-2000 standardized CPUE data suggested that gillnetting data were better suited for determining species apportionment than for estimating abundance (Reimer et al. 2002). In 2001, Chinook salmon abundance was estimated for the first time using a combination of Chinook catch proportions from the netting project and unfiltered passage estimates from the sonar project (Miller et al. 2003). Net-apportioned estimates of Chinook passage tracked well with conventional sonar passage estimates during the 2001 early run, but were substantially higher than the sonar estimates during the 2001 late run. The apparent under-representation of

sockeye salmon in the gillnet catches during the 2001 late run led to changes in the netting project beginning in 2002 that included using multiple mesh sizes (5.0" and 7.5" stretched; Reimer 2003, Reimer 2004a). For now, we assume these gillnets are not size selective.

In addition to developing an alternative index of Chinook abundance, we continued to pursue improved techniques for discriminating Chinook from sockeye salmon. An investigation conducted in 1999 (Burwen et al. 2000) attempted to identify alternative sites above tidal influence with stronger bank-orientation of sockeye salmon, where range thresholds would be more effective. The investigation concentrated on a site located at river km 21.2 (river mile 13.2) that was above tidal influence, but downstream of major spawning areas. Netting data indicated that there were fewer sockeye salmon in the offshore area at the alternative site than there were at the current site. However, there were still relatively large numbers of sockeye salmon present in the offshore area of the alternative site during peak migration periods as well as high numbers of Chinook salmon present in the nearshore area. The alternative sonar site also had several disadvantages over the current site including greater boat traffic, less acoustically favorable bottom topography, and increased background noise resulting in difficult fish tracking conditions.

Alternative methods for separating Chinook and sockeye salmon using acoustic information are also being pursued. Studies with tethered and free-swimming fish indicate that variables based on echo envelope length may provide higher discriminatory power than target strength for separating sockeye and Chinook salmon (Burwen and Fleischman 1998, Burwen et al. 2003). Statistical methods have been developed which enable robust estimates of species composition even when species overlap in size (Fleischman and Burwen 2003). In addition, ongoing experiments with DIDSON imaging sonar (Burwen et al. 2007) may provide a means to evaluate species classification techniques through comparison of split-beam generated fish traces with high-resolution images of fish provided by the DIDSON sonar.

## **PROJECT OBJECTIVES**

Objectives for 2004 were to generate daily and seasonal estimates of early-run (16 May-30 June) and late-run (1 July-5 August) Chinook salmon passage into the Kenai River using a split-beam sonar system.

## **METHODS**

### **STUDY AREA**

The Kenai River drainage is approximately 2,150 square miles. It is glacially influenced with discharge rates lowest during winter, increasing throughout the summer, and peaking in August (USDA 1992). The Kenai River has 10 major tributaries, many of which provide important spawning and/or rearing habitat for salmon. Tributaries include the Russian River, Skilak River, Killey River, Moose River, and Funny River.

The Kenai River drainage is located in a transitional zone between a maritime climate and a continental climate (USDA 1992). The geographic position and local topography influence both rainfall and temperature throughout the drainage. Average annual (1971-2000) precipitation for the City of Kenai, measured at the mouth of the Kenai River, is 48 cm. Average summer (June, July, and August) temperature for the City of Kenai is 12°C (WRCC 2003).

## **SITE DESCRIPTION**

The 2004 sonar site was located 14 km (8.5 mi) from the mouth of the Kenai River (Figure 2). This site has been used since 1985 and was selected for its acoustic characteristics and its location relative to the sport fishery and known spawning habitat of Chinook salmon.

The river bottom in this area has remained stable for the past 19 years despite a 140-year flood during September 1995 (Bosch and Burwen 1999). The slope from both banks has remained gradual and uniform, which allows a large proportion of the water column to be insonified without acoustic shadowing effects. On the right bank, the bottom is composed primarily of mud, providing an acoustically absorptive surface. This absorptive property improves the signal-to-noise ratio when the beam is aimed along the river bottom. The left-bank bottom gradient is steeper and consists of more acoustically reflective small rounded cobble and gravel.

The sonar site is located downstream of the lowest suspected spawning sites of Chinook salmon, yet far enough from the mouth that most of the fish counted are probably committed to the Kenai River (Alexandersdottir and Marsh 1990). Historically, almost all sport fishing occurred some distance upstream of this site. However, fishing activity near the site has increased over the past several years, mostly during the late run.

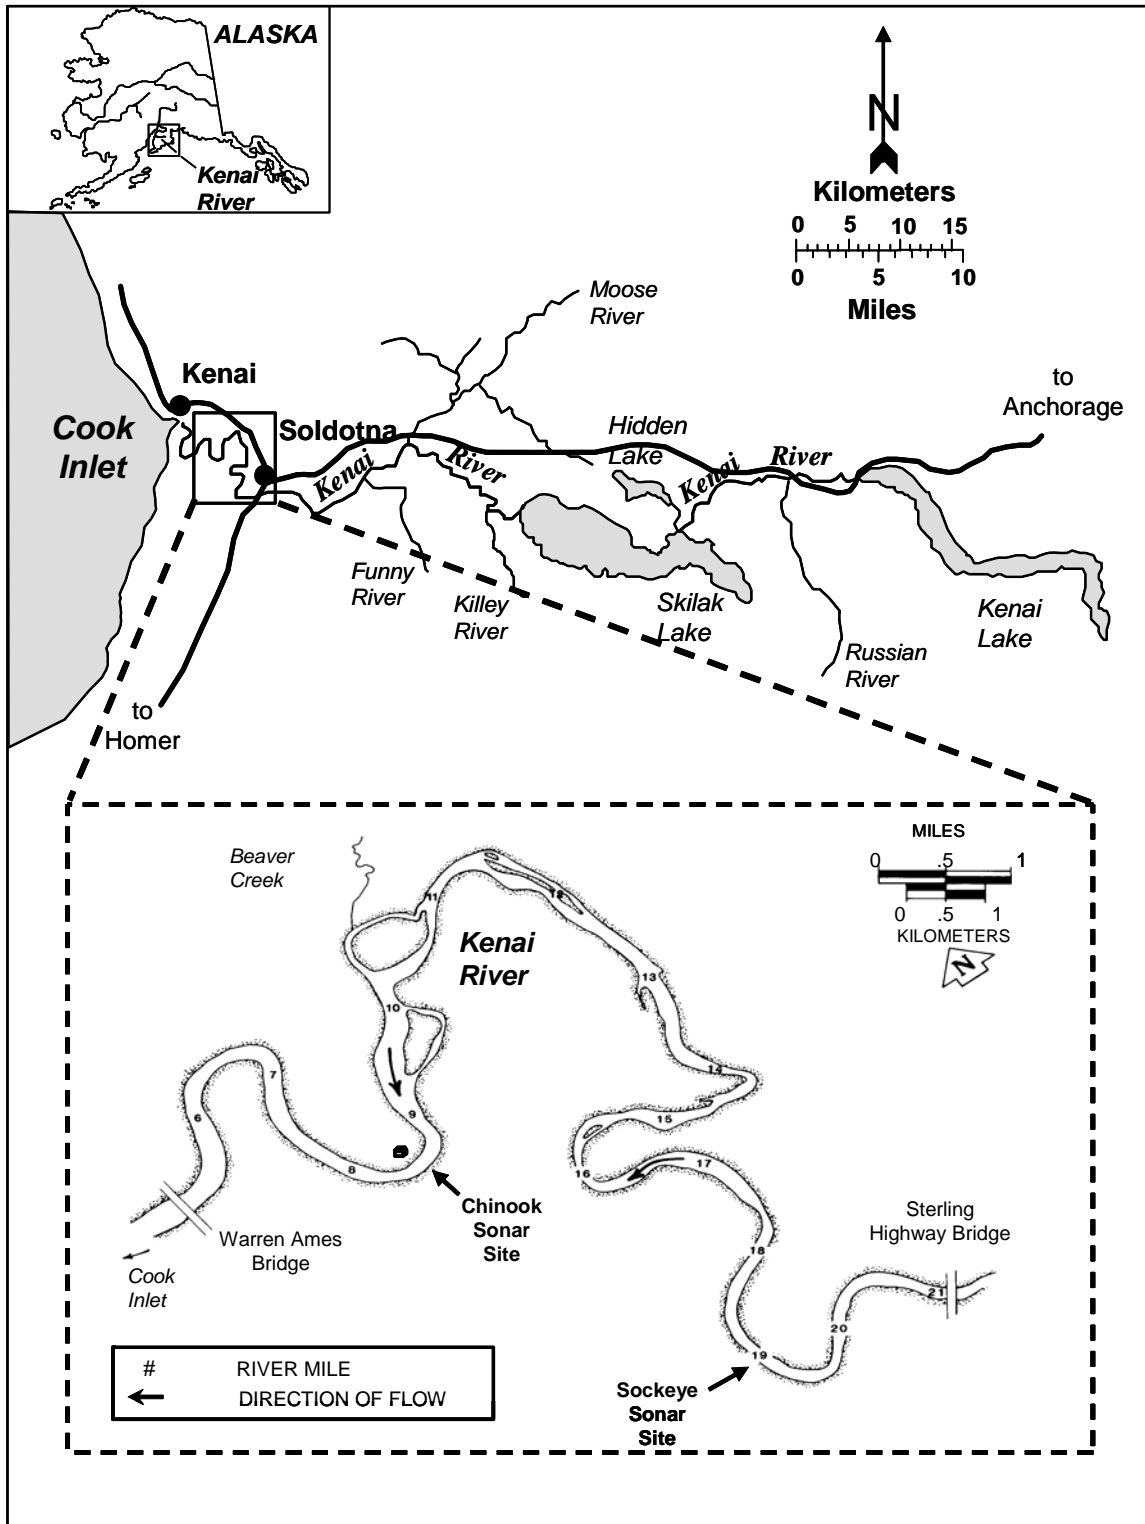

## **ACOUSTIC SAMPLING**

A Hydroacoustic Technology Inc. (HTI) split-beam sonar system was operated from 16 May to 5 August 2004. Components of the system are listed in Table 1 and further described in HTI manuals (HTI 1996, 1997). A brief explanation of the theory of split-beam sonar and its use in estimating target strength can be found in Appendix A1. A detailed explanation can be found in Ehrenberg (1983).

## **Sonar System Configuration**

Sampling on both banks was controlled by electronics housed in a tent located on the right bank of the river. Communication cables were connected to transducers and their aiming devices on both banks. Cables leading to the left-bank equipment were suspended above the river at a height that would not impede boat traffic (Figure 3). Steel tripods were used to deploy the transducers offshore. One elliptical, split-beam transducer was mounted horizontally (side-looking) on each tripod. At the start of the season the transducer tripods were placed on each bank in a position close to shore but still submerged at low tide. From 16 May to 5 August, water level at low tide rose approximately 1.1 m. Rising water level throughout the season and heavy debris accumulation on the gear resulted in occasional relocation of transducer tripods. Total insonified range by both (right and left) sonar beams ranged from a low of approximately 62 m on 17-18 July to a high of 86 m on 29 June (Figure 4).

Vertical and horizontal aiming of each transducer was remotely controlled by a dual-axis electronic pan and tilt system. A digital readout showed the aiming angle in the vertical and horizontal planes. In the vertical plane, the transducer was aimed using an oscilloscope and chart recorder to verify that the sonar beam was grazing the river bottom. In the horizontal plane, the transducer was aimed perpendicular to the flow of the river to maximize probability of insonifying fish from a lateral aspect. The range encompassed by each transducer was determined by the river bottom contour and the transducer placement. Transducers were placed in such a manner as to maximize counting range in an attempt to fully insonify the cross section of the river between the right- and left-bank transducers.

System Component	Description
Sounder	Hydroacoustics Technology Inc. (HTI) Model 244 Split-Beam Echo sounder operating at 200 kHz
Data Processing Computer	Dell Dimension 2350 personal computer
Transducers	(2) HTI Split-Beam transducers: Left Bank: nominal beam widths: $2.9^{\circ} \times 10.2^{\circ}$ Right Bank: nominal beam widths: $2.8^{\circ} \times 10.0^{\circ}$
Chart Recorder	HTI model 403 digital dual-channel chart recorder
Oscilloscope	Nicolet model 310 digital storage oscilloscope
Video Display	Hydroacoustic Assessments HARP-HC
Remote Pan and Tilt	Remote Ocean Systems Model PTC-1 Pan and Tilt Controller
Aiming Controller	
Remote Pan and Tilt	Remote Ocean Systems Model PT-25 Remote Pan and Tilt Unit
Aiming Unit	
Heading and Angular Measurement Device	JASCO Research Ltd. Uwinstu Underwater Measurement Device.

### Bottom Mapping and Beam Coverage

A detailed profile of the river bottom and the area encompassed by the sonar beams was produced prior to acoustic sampling. Depth readings from a Lowrance X-16 were paired with range (distance) measurements from a fixed target on shore using a Bushnell Laser Ranger ( $\pm 1$  m accuracy). When bottom profile information is combined with information from the attitude sensor, a detailed visualization of how the water column above the bottom substrate was insonified by the acoustic beam could be generated (Figure 5).

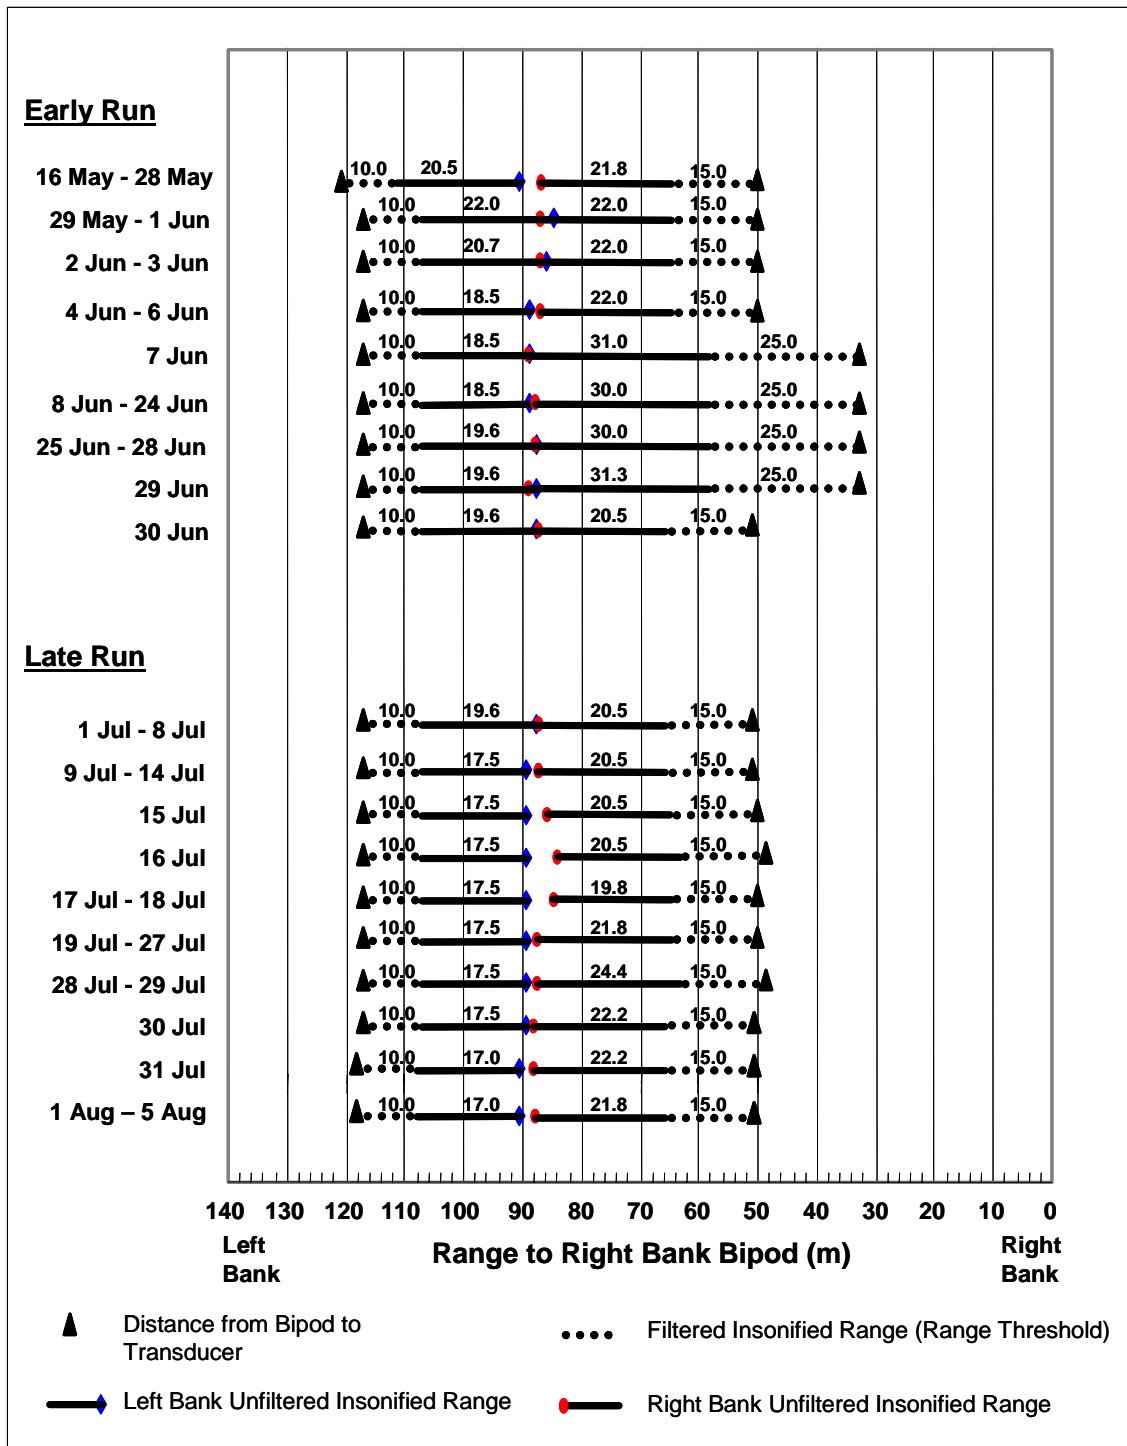

Each time the transducer was moved, new measurements of the transducer height above the bottom substrate and its position relative to a fixed shore location were updated in an EXCEL worksheet so that beam coverage at the new location could be evaluated.

Before 2001, the right- and left-bank transducers were deployed directly across the river from each other, and complete beam coverage for the entire middle portion of the river was accomplished by extending the counting range for both banks to the thalweg. Under these conditions, we could be relatively certain that the entire middle portion of the river was insonified. In 2001, river bottom profiles indicated improved beam coverage (in the vertical plane) could be attained on the left bank by moving the transducer approximately 35 m downstream of its original location (Miller et al. 2003). The left-bank transducer has been deployed at this location since 2001. Because of the offset deployment of the right- and left-bank transducers (Figure 3), it is difficult to determine if there is complete beam coverage to the thalweg (Miller et al. 2004).

**Figure 3.**-Cross-sectional (top) and aerial (bottom) diagrams of sonar site illustrating insonified portions of the Kenai River, 2004.

Note: Distance from bipod to thalweg is approximately 88 m.

**Figure 4.**-Daily right and left bank transducer placement and insonified ranges relative to bipod tower located on the right bank, Kenai River, 2004.

**Figure 5.**-Bottom profiles by bank for the Kenai River Chinook sonar site with approximate transducer placement and sonar beam coverage for 16 May 2004.

## System Calibration

HTI performed reciprocity calibrations with a naval standard transducer on 3 December 2003. Calibration results were verified at the calibration facility with a 38.1-mm tungsten carbide sphere (Foote and MacLennan 1984). Further verification was obtained *in situ* by measuring the same standard sphere on 13 May, 9 July, 12 July, and 3 August. For each standard sphere measurement, we recorded the maximum background noise level and voltage threshold in addition to the data collected automatically by the onboard signal-processing software (see Data Acquisition).

## Sampling Procedure

A systematic sample design (Cochran 1977) was used to sample from each bank for 20 min each hour. Although the sonar system is capable of sampling both banks continuously, data collection was restricted to 20-min samples per hour to limit the data processing time and personnel required to produce daily fish passage estimates. The equipment was automated to sample the

right bank for 20 min starting at the top of each hour followed by a 20-min left-bank sample. The system was quiescent or activated for ancillary studies during the third 20-min period. This routine was followed 24 hours per day and 7 days per week unless one or both banks were inoperable.

A test of this sample design conducted in 1999 found no significant difference between hourly estimates of Chinook salmon passage obtained using 1-hour counts and estimates obtained by extrapolating 20-min counts (Miller et al. 2002).

Because fish passage rates are related to tide stage (Eggers et al. 1995), tide stage was recorded at the top of each hour and at 20 minutes past each hour to coincide with the start of sonar sampling. Tide stage was recorded using water level measurements taken from a staff gauge at the sonar site.

### **Echo Sounder Settings**

Relevant echo sounder settings are listed in Table 2 with complete summaries by bank in Appendices B1 and B2. Most echo sounder settings were identical for each bank and remained consistent throughout the sample period. High power and low gain settings were used to maximize SNR. The transmitted pulse width was set relatively low to maximize resolution of individual fish, and SNR.

**Table 2.**-HTI model 244 digital echo sounder settings used in 2004.

Echo Sounder Parameters	Value
Transmit Power	25 dB
System Gain ( $G_r$ )	-18 dB
TVG	$40\log_{10}R$
Transmitted Pulse Width	0.20 msec
Ping Rate Right Bank	11 pings/sec
Ping Rate Left Bank	16 pings/sec

### **Data Acquisition**

An HTI Model 244 digital echo sounder (DES) performed the initial filtering of returned echoes based on user-selected criteria (Table 3, Appendices B1 and B2) that are input via software stored on an external data processing computer (Table 1, Figure 6). The DES recorded the start time, date, and number of pings processed for each sample.

Echoes in the transducer near field ( $\leq 2.0$  m) were excluded (MacLennan and Simmonds 1992), as were echoes which exceeded maximum vertical and horizontal angles off-axis. Angle filters were used to prevent consideration of unreliable data from transducer side lobes.

Voltage thresholds for data acquisition were set high enough to exclude most background noise from spurious sources such as boat wake, the river bottom, and the water surface. Collection of data from unwanted noise creates data management problems and also makes it difficult to distinguish echoes originating from valid fish targets. The amount of background noise is determined largely by the dimensions of the sonar beam in relation to the depth of the river. Since the water level at the sonar site is strongly influenced by tidal stage (vertical fluctuations of more than 4 m), the amount of background noise fluctuates periodically, with lowest noise levels

**Table 3.**-Echo acceptance criteria for digital echo processing, 2004.

Bank	Pulse width <sup>a</sup> (ms) at -6 dB	Vertical angle off-axis (°)	Horizontal angle off-axis(°)	Threshold mV (dB)	Minimum Range (m)
Right					
16-May to 5-Aug	0.04 to 10.0	-2.5 to 2.0	-5.0 to 5.0	713 (-35 dB)	2.0
Left					
16-May to 5-Aug	0.04 to 10.0	-2.5 to 2.0	-5.0 to 5.0	451 (-35 dB )	2.0

<sup>a</sup> Pulse width filters have not been used since 1996 (Burwen and Bosch 1998) in order to retain information potentially useful for species classification (Burwen et al. 2003; Fleischman and Burwen 2003).

during high tide and the highest levels during falling and low tides. Voltage thresholds corresponding to a -35 dB target on-axis were selected for each bank as the lowest threshold that would exclude background noise at low tide when noise was at a maximum.

For each echo passing initial filtering criteria, the DES wrote information in ASCII file format (\*.RAW files). This file provided a record of all raw echo data, which could then be used by other post-processing software. A uniquely-named file was produced for each sample hour and stored the following statistics for each tracked echo: (1) distance from the transducer, (2) sum channel voltage produced by the echo, (3) pulse widths measured at -6 dB, -12 dB, and -18 dB down from the peak voltage, (4) up-down (vertical) angle, left-right (horizontal) angle, and (5) multiplexer port.

The sum channel voltage from the DES was also output to a printer, to a Nicolet 310<sup>1</sup> digital storage oscilloscope, and to a Harp HC2 color chart monitor. Output to the printer was filtered only by a voltage threshold, which was set equal to the DES threshold. Real-time echograms were produced for each sample. The echograms were used for data backup and transducer aiming, and to aid in manual target tracking. Voltage output to the oscilloscope and color monitor was not filtered. Monitoring the unfiltered color echogram ensured that subthreshold targets were not being unintentionally filtered. Advanced features on the digital oscilloscope aided in performing field calibrations with a standard target and in monitoring the background noise level relative to the voltage threshold level.

## **FISH TRACKING AND ECHO COUNTING**

Using HTI proprietary software called TRAKMAN, echoes (in the \*.RAW files) were manually grouped (tracked) into fish traces. TRAKMAN produces an electronic chart recording for all valid echoes collected during a 20-min sample. Selected segments of the chart can be enlarged and echoes viewed on a Cartesian grid. Echoes following a sequential progression through the beam were selected by the user and classified into fish traces. TRAKMAN then produced three output files. The first file contained each echo that was tracked in a valid target (\*.MEC file) and included the following data for each echo: estimated X (left-right), Y (up-down), and Z (distance from the transducer) coordinates in meters, where the transducer face is the origin of

<sup>1</sup> Product names used in this report are included for scientific completeness but do not constitute a product endorsement.

the coordinate system; pulse widths measured at -6 dB, -12 dB, and -18 dB amplitude levels; combined beam pattern factor in dB; and target strength in dB. The second fixed-record ASCII file (\*.MFS file) summarized data from all echoes associated with an individual tracked target and output the following fields by target: total number of echoes tracked; starting X, Y, and Z coordinates; distance traveled (meters) in the X, Y, and Z directions; mean velocity (m/sec); and mean target strength (dB). The third file was identical to the \*.RAW file described above except that it contained only those echoes combined into tracked targets. Direction of travel was estimated by calculating the simple linear regression of X-axis position (distance up- or down-river from the beam axis) on ping number, for echoes with absolute X-axis angle less than 5 degrees. On the right bank, a target was classified as upstream-bound if the slope of the regression was negative or downstream-bound if the slope was positive. On the left bank the criteria were reversed. A diagram illustrating data flow can be found in Appendix C1.

Downstream targets (and occasionally upstream targets during a strong flood tide) were further classified as fish or debris primarily by looking at the angle of passage and degree of movement in the Z-axis (distance from transducer) as the target moved through the acoustic beam. For debris, the angle of passage through the beam is constant with little change in the range as it passes through the beam. Consequently, debris resembles a line drawn on the echogram with a straightedge. A fish typically leaves a meandering trace that reflects some level of active movement as it passes through the acoustic beam. Obvious debris-like targets were excluded from consideration as valid fish targets during the tracking procedure and the remaining downstream targets were retained to adjust the total estimate of fish passage. Separate summary files were generated for tracked targets classified as debris (i.e. \*.DEC and \*.DFS files). Except for debris, only targets comprising echoes displaying fish-like behavior were tracked. Echoes from structure, boat wake and sport fishing tackle were ignored.

## **DATA ANALYSES**

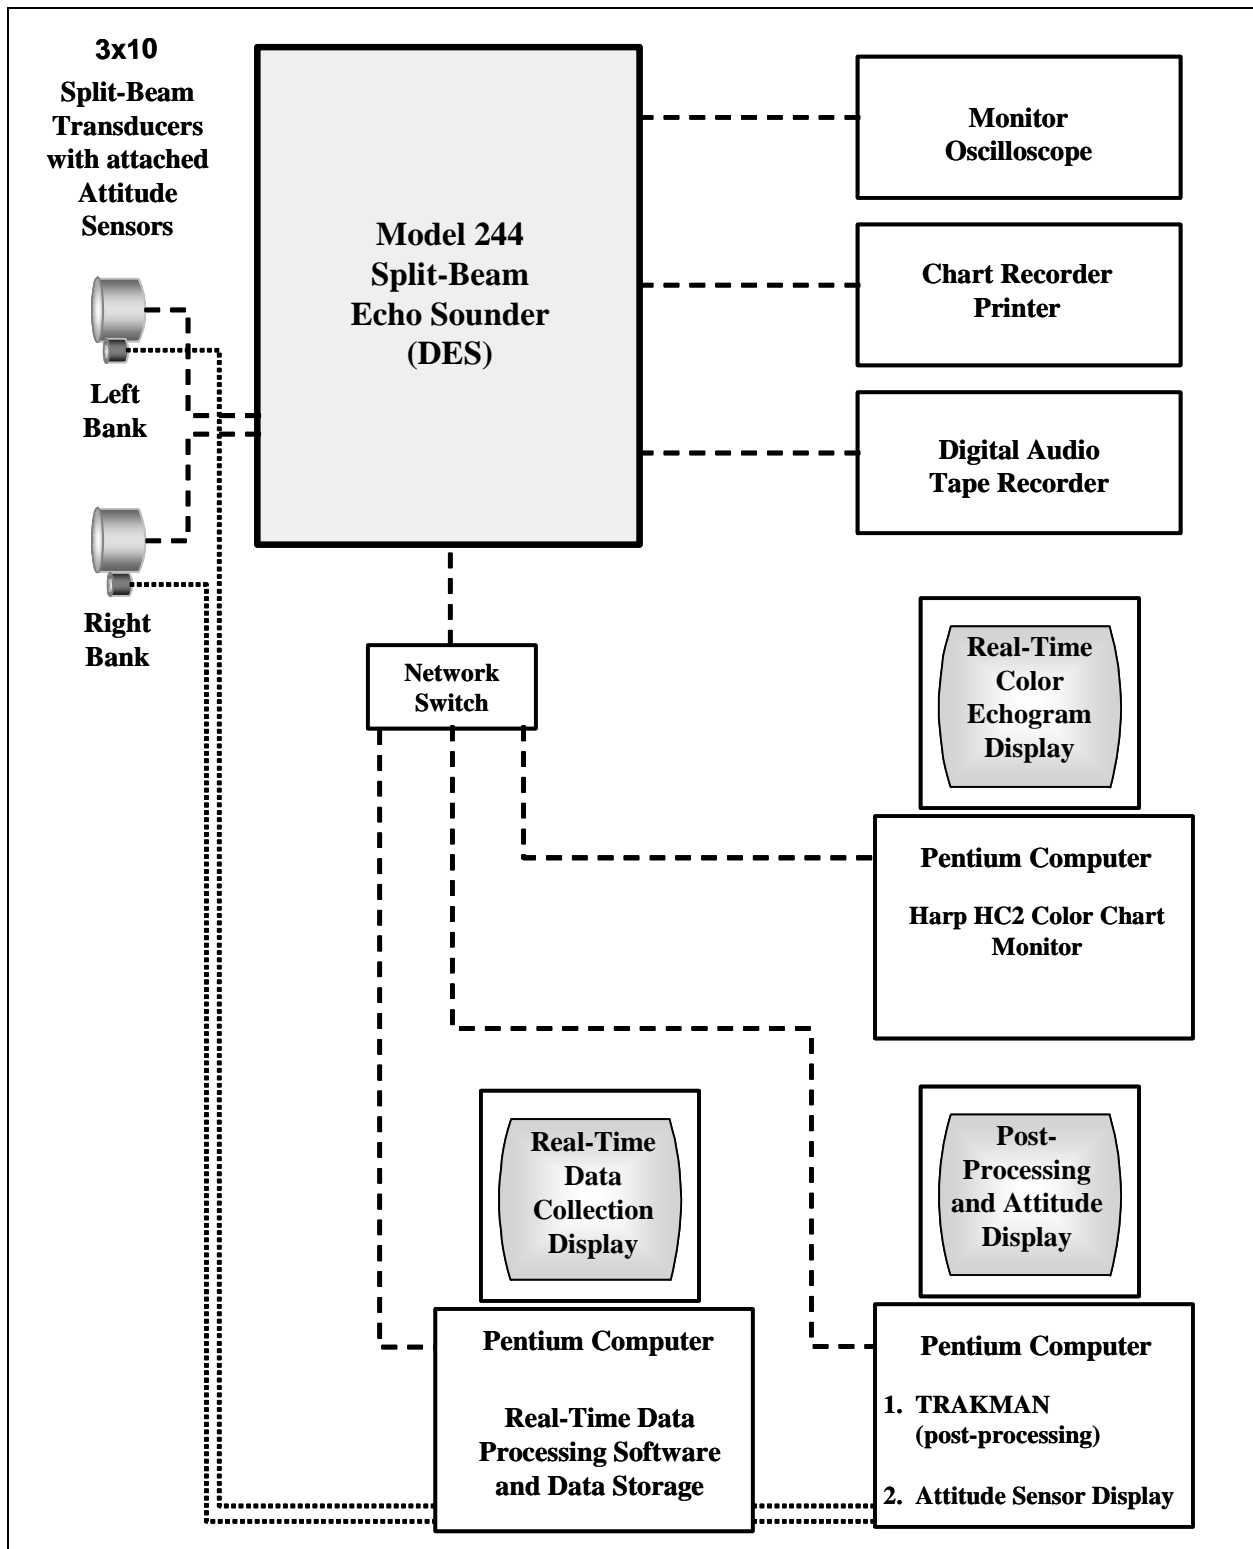

### **Tidal and Temporal Distribution**

Falling tide was defined as the period of decreasing staff-gauge readings, low tide as the period of low static readings, and rising tide as the period of both increasing readings and high static readings (i.e., high slack tide). The rising and high slack tides were combined into one category because of the very short duration of high slack tide at the sonar site. Data from both banks were combined to summarize fish passage by tide stage (falling, low, and rising) for both upstream and downstream traveling fish. Data were first filtered using target strength and range criteria (see section below on species discrimination).

### **Spatial Distribution**

Knowledge of the spatial distribution of fish is desirable for developing strategies for insonifying a specific area, for determining appropriate transducer beam dimensions, and for evaluating the probability of detecting fish near the edge of the acoustic beam (Mulligan and Kieser 1996).

Fish range (z-axis) distributions for each bank were plotted separately for upstream and downstream moving targets. Fish range distributions were calculated using the mean distance from transducer for each target. Before 2000, range distribution comparisons were made using  $z_m$ , the distance from the face of the transducer to the target location (Miller et al. 2002). These comparisons provided information on distribution of fish targets from the face of the transducer, but because transducer locations changed throughout the season the comparisons were poor

**Figure 6.**-Diagram of 2004 split-beam sonar system configuration and data flow.

descriptors of actual fish range distributions across the river. Beginning in 2000, estimates of distance from bank were standardized to the nearest shore transducer deployment for that bank based on distances to a fixed point (cable bipod) on the right bank (Figures 3 and 4):

$$z_a = z_m + |z_t - z_n|, \quad (1)$$

where:

- $z_a$  = adjusted range (in meters),
- $z_t$  = distance (in meters) from right bank bipod to transducer, and
- $z_n$  = distance (in meters) from right bank bipod to nearest shore (right bank or left bank) deployment location.

Fish range distribution plots were produced with the adjusted (standardized) range estimates allowing for comparisons of actual fish target locations across the river. The end range in these distribution graphs was the maximum distance covered (generally to the thalweg) by the sonar beam on that particular bank.

Vertical distributions were plotted by direction of travel (up- and downstream) and tide stage. Vertical distributions were calculated from the midpoint angle off-axis in the vertical plane as follows:

$$\theta_y = \arcsin \frac{y_s + \left( \frac{d_y}{2} \right)}{z_m}, \quad (2)$$

where:

- $\theta_y$  = vertical angle-off-axis midpoint (degrees),
- $y_s$  = starting vertical coordinate (in meters), and
- $d_y$  = distance traveled in vertical direction (in meters).

### Target Strength Distribution

Target strength was calculated for individual echoes (Appendix A1) and averaged for each tracked fish. Target strength distributions were plotted separately for early- and late-run fish and for upstream and downstream moving fish.

### Species Discrimination

Tracked fish were filtered using criteria to minimize the number of sockeye salmon counted. Two parameters have been used historically on this project to distinguish large Chinook salmon from sockeye salmon and other species: target strength (-28 dB threshold) and distance from the transducer (range). The vast majority of sockeye salmon swims near shore, and can be excluded by simply counting offshore targets. Although we know that filters based on target strength and range are not always effective at excluding all sockeye salmon (Burwen et al. 1995; Eggers 1994), we continue their use for historical comparability, while we investigate other means of discriminating between fish sizes (see Discussion).

Range thresholds differed by bank and over time. Range thresholds were changed when transducers were moved or when fish distribution and behavior indicated that species discrimination could be improved. Early-run range thresholds were 10 m (16 May–30 June) on the left bank and 15 m (16 May–6 June and 30 June) and 25 m (7 June–29 June) on the right bank (Figure 4). Late-run (1 July–5 August) range thresholds were 10 m on the left bank and 15 m on the right bank (Figure 4).

Targets observed passing the sonar site in pairs or small groups were assumed to be sockeye salmon. During periods of high sockeye salmon passage, size and range filters failed to remove many of these targets. As a result, hourly samples containing substantial numbers of paired or grouped targets beyond the range thresholds were considered unreliable and were excluded from calculation of the Chinook passage estimate (Appendix D1). This reduced the potential for overestimating Chinook salmon passage, at the risk of underestimating passage. If Chinook passage was relatively high in the excluded samples, then Chinook passage estimates would be biased conservatively low.

### Passage Estimates

Estimates of Chinook salmon passage for day  $i$  were generated as follows:

$$\hat{y}_i = 24 \sum_{k=1}^2 \bar{y}_{ik} , \quad (3)$$

where the mean hourly passage past bank  $k$  during day  $i$  was:

$$\bar{y}_{ik} = \frac{1}{n_{ik}} \sum_j^{n_{ik}} \hat{y}_{ijk} , \quad (4)$$

where  $n_{ik}$  was the number of hours during which passage was estimated on bank  $k$  for day  $i$ .

Hourly Chinook salmon passage on bank  $k$  during hour  $j$  of day  $i$ , was estimated as follows:

$$\hat{y}_{ijk} = \frac{60}{t_{ijk}} c_{ijk} , \quad (5)$$

where:

$t_{ijk}$  = number of minutes (usually 20) sampled from bank  $k$  during hour  $j$  of day  $i$ , and

$c_{ijk}$  = number of upstream-bound fish on bank  $k$  meeting range and target-strength criteria during  $t_{ijk}$ .

When the sonar system was functional on one bank but not the other, we estimated passage on the non-functional bank  $k$  from passage on the functional bank  $k'$  with a ratio estimator:

$$\hat{y}_{ijk} = \hat{R}_{ikt} \hat{y}_{ijk'} , \quad (6)$$

where the estimated bank-to-bank ratio  $R_{ikt}$ , for day  $i$  and tide stage  $t$  was calculated by pooling counts from all hours during the previous 2 days (to ensure adequate sample size) with tide stage  $t$ :

$$\hat{R}_{ikt} = \frac{\sum_{j \in J_t} \hat{y}_{(i-2)jk} + \sum_{j \in J_t} \hat{y}_{(i-1)jk}}{\sum_{j \in J_t} \hat{y}_{(i-2)jk'} + \sum_{j \in J_t} \hat{y}_{(i-1)jk'}}. \quad (7)$$

The variance of estimates of  $y$ , due to systematic sampling in time, was approximated (successive difference model; Wolter 1985), with adjustments for missing data, as:

$$\hat{V}[\hat{y}_i] \cong 24^2(1-f) \sum_{k=1}^2 \frac{\sum_{j=2}^{24} \phi_{ijk} \phi_{i(j-1)k} (\hat{y}_{ijk} - \hat{y}_{i(j-1)k})^2}{2 \sum_{j=1}^{24} \phi_{ijk} \sum_{j=2}^{24} \phi_{ijk} \phi_{i(j-1)k}}, \quad (8)$$

where  $f$  was the sampling fraction (approximately 0.33), and  $\phi_{ijk}$  was 1 if the sonar was operating on bank  $k$  during hour  $j$  or 0, if not. Uncertainty due to imperfect detection of fish, imperfect discrimination of species, missing hourly counts, and spatial expansion was not estimated. Therefore, variance estimates were biased low.

The cumulative estimate of Chinook salmon abundance, and its variance, was the sum of the daily estimates:

$$\hat{Y} = \sum_i \hat{y}_i, \text{ and} \quad (9)$$

$$\hat{V}[\hat{Y}] = \sum_i \hat{V}[\hat{y}_i]. \quad (10)$$

Late-run passage through 10 August ( $\hat{Y}_e$ ) was estimated by dividing by the mean proportion of passage ( $\bar{p}$ ) through 5 August for the 10 years (1987-1988, 1990, 1992-1993, 1995, and 1998-2001) when the sonar project operated through at least 9 August:

$$\hat{Y}_e = \frac{\hat{Y}}{\bar{p}}, \quad (11)$$

where:

$$\bar{p} = \frac{\sum p_g}{10}, \quad (12)$$

$$p_g = \frac{\sum_{i=1 \text{ July}}^{5 \text{ Aug}} \hat{y}_i}{\sum_{i=1 \text{ July}}^{10 \text{ Aug}} \hat{y}_i}, \quad (13)$$

and  $g$  was the year. The variance of  $\hat{Y}_e$  was:

$$\hat{V}[\hat{Y}_e] = \hat{V}[\hat{Y}]\bar{p}^{-2} + \hat{V}[\bar{p}^{-1}]\hat{Y}^2 - \hat{V}[\hat{Y}]\hat{V}[\bar{p}^{-1}], \quad (14)$$

where:

$$\hat{V}[\bar{p}^{-1}] = \frac{\sum_{g=1}^{10} (p_g^{-1} - \bar{p}^{-1})^2}{10(10-1)}. \quad (15)$$

Unfiltered<sup>2</sup> daily passage estimates for day  $i$ ,  $\hat{x}_i$ , were calculated by following equations 3-10 after substituting unfiltered counts  $c'_{jk}$  for  $c_{jk}$ , where:

$c'_{jk}$  = number of upstream-bound fish greater than 15 m from the right-bank transducer and greater than 10 m from the left-bank transducer, for bank  $k$  and hour  $j$ .

The “alternative” daily estimate (or net-apportioned estimate) of Chinook salmon abundance was calculated by multiplying the unfiltered sonar passage estimate by the proportion  $\hat{q}_i$  of Chinook salmon in drift gillnet catches near the sonar site (Reimer *In prep.*):

$$\hat{y}'_i = \hat{x}_i \hat{q}_i. \quad (16)$$

The variance estimate of the alternative estimate follows Goodman 1960:

$$\text{var}(\hat{y}'_i) = \hat{x}_i^2 \text{var}(\hat{q}_i) + \hat{q}_i^2 \text{var}(\hat{x}_i) - \text{var}(\hat{q}_i) \text{var}(\hat{x}_i). \quad (17)$$

Note that variance of sonar estimates presented in this report reflects only the uncertainty associated with sampling error, as this is the only uncertainty we are currently able to quantify. Other sources of uncertainty associated with this type of project include target detection, species composition, direction of travel, and target tracking. Because we are only able to account for sampling error related to the systematic sample design, our approach has been to keep the methods as consistent as possible from year to year so that any bias will also be consistent.

## RESULTS

### SYSTEM CALIBRATION

During system calibration at the HTI calibration facility, target strength of the 38.1-mm tungsten carbide standard sphere was measured at -39.7 dB with the right-bank transducer and -39.1 dB with the left-bank transducer (HTI 2003; Table 4). The theoretical value for the sphere is -39.5 dB (MacLennan and Simmonds 1992). During subsequent *in situ* calibration checks using the same sphere, mean target strength varied from -37.5 dB to -38.9 dB on the right bank and from -37.4 dB to -40.0 dB on the left bank (Table 4). Small fluctuations in mean target strength are expected throughout the season during *in situ* calibration checks as target strength can vary with signal-to-noise ratio, water temperature, depth, conductivity and other factors.

### TARGET TRACKING

In 2004, 70,584 targets were manually tracked, 13,414 during the early run and 57,170 during the late run. After filtering for range and target strength criteria and making temporal

---

<sup>1</sup> Unfiltered with respect to target strength, but restricted to upstream-bound targets passing at a distance greater than the smallest range thresholds used during the season (15 m on right bank, 10 m on left bank).

expansions, the proportion of upstream moving fish was 95% for the early run and 96% for the late run (Appendices E1 and E2). The daily proportion of upstream moving Chinook salmon in 2004 ranged from 80% to 100% during the early run and 91% to 99% during the late run.

Echo counts per fish (filtered for range and target strength criteria) varied by run, bank, and direction of travel. Upstream moving Chinook averaged 77 (SD = 61) echoes per fish on the left bank during the early run and 95 (SD = 60) echoes on the right bank. Downstream moving Chinook averaged 81 (SD = 76) echoes on the left bank and 110 (SD = 105) echoes on the right bank. During the late run, upstream moving Chinook averaged 94 (SD = 63) echoes on the left bank and 72 (SD = 48) echoes on the right bank. Downstream moving Chinook averaged 130 (SD = 115) echoes on the left bank and 109 (SD = 97) echoes per fish on the right bank.

**Table 4.**—Results of 2004 *in situ* calibration verifications using a 38.1 mm tungsten carbide standard sphere.

## TIDAL AND TEMPORAL DISTRIBUTION

Upstream Chinook passage during both the early and late runs occurred mostly during the falling tide (50.2% and 52.9%, respectively; Tables 5 and 6, Figure 7). Early-run downstream passage was similar between the rising (37.8%) and falling (41.1%) tides, while late-run downstream passage occurred primarily during the falling tide (56.1%).

## SPATIAL DISTRIBUTION

### Vertical Distribution

Chinook salmon were bottom-oriented during both runs, although vertical distribution did vary somewhat by direction of travel, tide stage, and season (Appendices F1 and F2). During the

**Table 5.**-Estimates of Chinook salmon passage by tide stage and direction of travel for the 2004 early run (16 May to 30 June).

early run, 87% of the upstream moving Chinook salmon on the left bank and 85% on the right bank were on or below the acoustic axis (Figure 8). Downstream moving Chinook salmon were less bottom-oriented (Appendix F1). Seventy-one percent of downstream moving fish on the left bank and 79% on the right bank were below the acoustic axis (Figure 8). Upstream moving fish on the left bank (mean =  $-0.44^\circ$ , SD = 0.48,  $n = 2,018$ ) were on average lower ( $t = 3.55$ ,  $P < 0.001$ ) in the water column than downstream moving fish (mean =  $-0.25^\circ$ , SD = 0.52,  $n = 79$ ). Similarly, upstream moving fish on the right bank (mean =  $-0.29^\circ$ , SD = 0.36,  $n = 3,625$ ) were lower in the water column ( $t = 3.27$ ,  $P < 0.001$ ) than downstream fish (mean =  $-0.20^\circ$ , SD = 0.43,  $n = 229$ ). Upstream traveling fish on both banks were bottom-oriented during all tide phases, but were distributed slightly higher in the water column during rising tides (Figure 9).

Late-run Chinook salmon also showed a tendency to travel along the river bottom (Figure 10 and Appendix F2). Eighty-seven percent of upstream moving fish on the left bank and 88% of upstream moving fish on the right bank were on or below the acoustic axis. Downstream

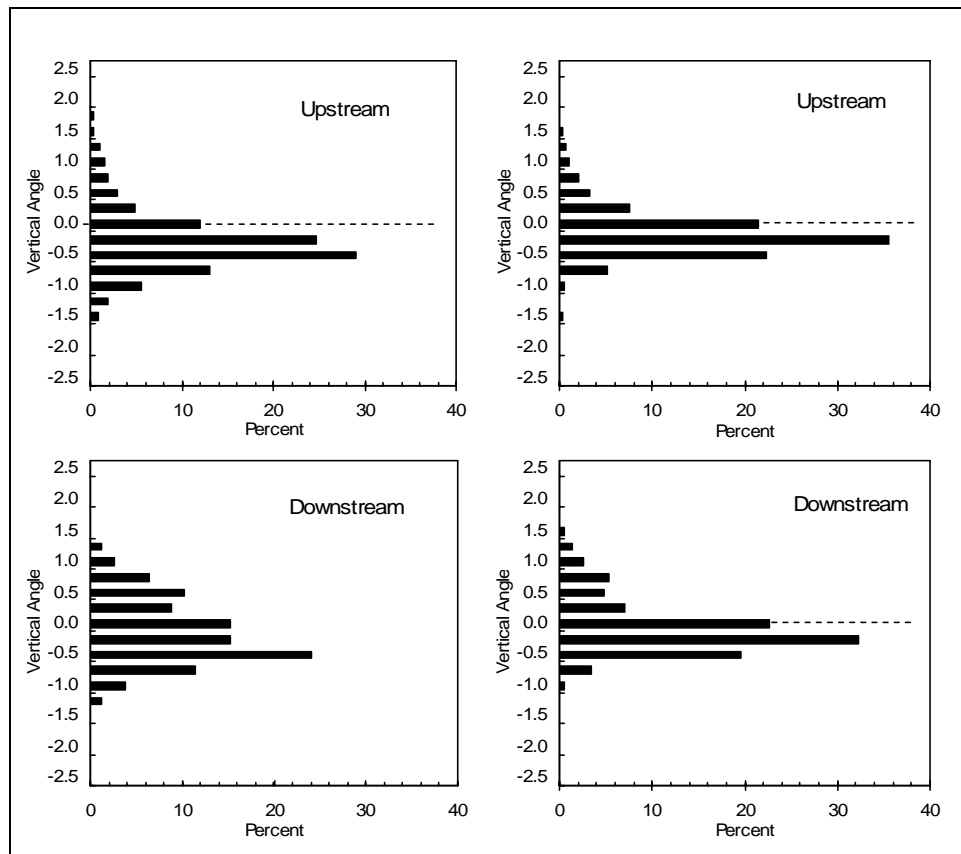

Note: Data have been filtered by range (distance from transducer) and target strength criteria.

**Figure 7.**—Percent of upstream and downstream moving Chinook salmon by tide stage during the early (top) and late (bottom) runs, Kenai River, 2004.

traveling fish were slightly higher in the water column (Appendix F2). Eighty-three percent of downstream moving fish on the left bank and 84% on the right bank were on or below the acoustic axis. Upstream moving fish on the left bank (mean =  $-0.40^\circ$ , SD = 0.39,  $n = 8,723$ ) traveled lower ( $t = 2.18$ ,  $P = 0.015$ ) in the water column than downstream fish (mean =  $-0.36^\circ$ , SD = 0.40,  $n = 362$ ). Similarly, upstream moving fish on the right bank (mean =  $-0.32^\circ$ , SD = 0.33,  $n = 18,204$ ) traveled lower ( $t = 4.67$ ,  $P < 0.001$ ) in the water column than downstream fish (mean =  $-0.25^\circ$ , SD = 0.36,  $n = 711$ ). Vertical distribution of upstream traveling fish was slightly higher during rising tides on both the left and right bank (Figure 11).

## Range Distribution

During the early run, upstream traveling Chinook were distributed throughout the insonified range on both the left and right bank (Figure 12). Fish range distributions were relatively similar among the three tide stages on the left bank (Figure 13). On the right bank, the bimodal range distribution during the falling and low tides was more pronounced than during the rising tide (Figure 13).

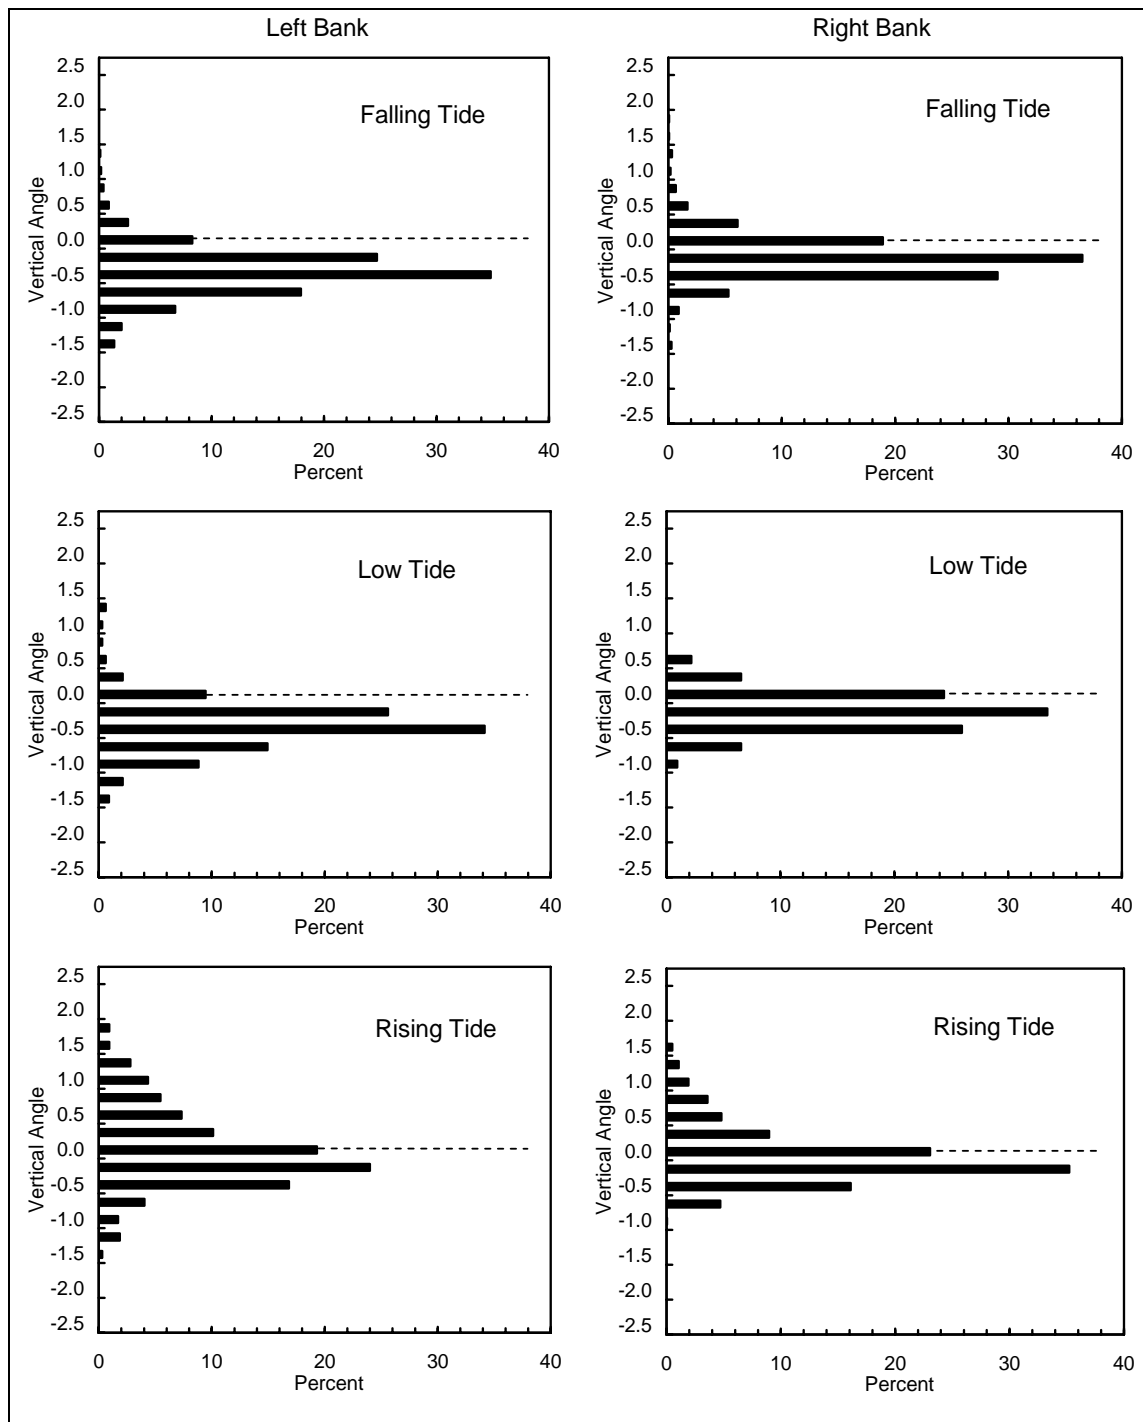

Note: Data have been filtered by range (distance from transducer) and target strength criteria. Acoustic axis = 0.0.

**Figure 8.**-Vertical distributions above and below the acoustic axis of early-run upstream and downstream moving Chinook salmon by bank, Kenai River, 2004.

During the late run, upstream traveling Chinook were again distributed throughout the insonified range on both banks, while downstream traveling fish were distributed primarily offshore (Figure 14). Bimodal range distributions of upstream moving fish were observed on both banks during the falling and low tide stages (Figure 15). Peak passage during these tide stages on the right bank occurred near the beginning and end of the insonified range. During the rising tide, upstream fish distribution was more evenly distributed (Figure 15).

Estimates of upstream Chinook salmon passage by bank were higher for the right bank during both the early and late run (Tables 7 and 8). During the early run 62% of upstream passage was estimated to occur on the right bank while 38% occurred on the left bank (Table 7). During the late run 63% of upstream passage was estimated to occur on the right bank and 37% on the left bank (Table 8).

Note: Data have been filtered by range (distance from transducer) and target strength criteria.  
Acoustic axis = 0.0.

**Figure 9.**-Vertical distributions above and below the acoustic axis of early-run upstream moving Chinook salmon by tide stage and bank, Kenai River, 2004.

Note: Data have been filtered by range (distance from transducer) and target strength criteria. Acoustic axis = 0.0.

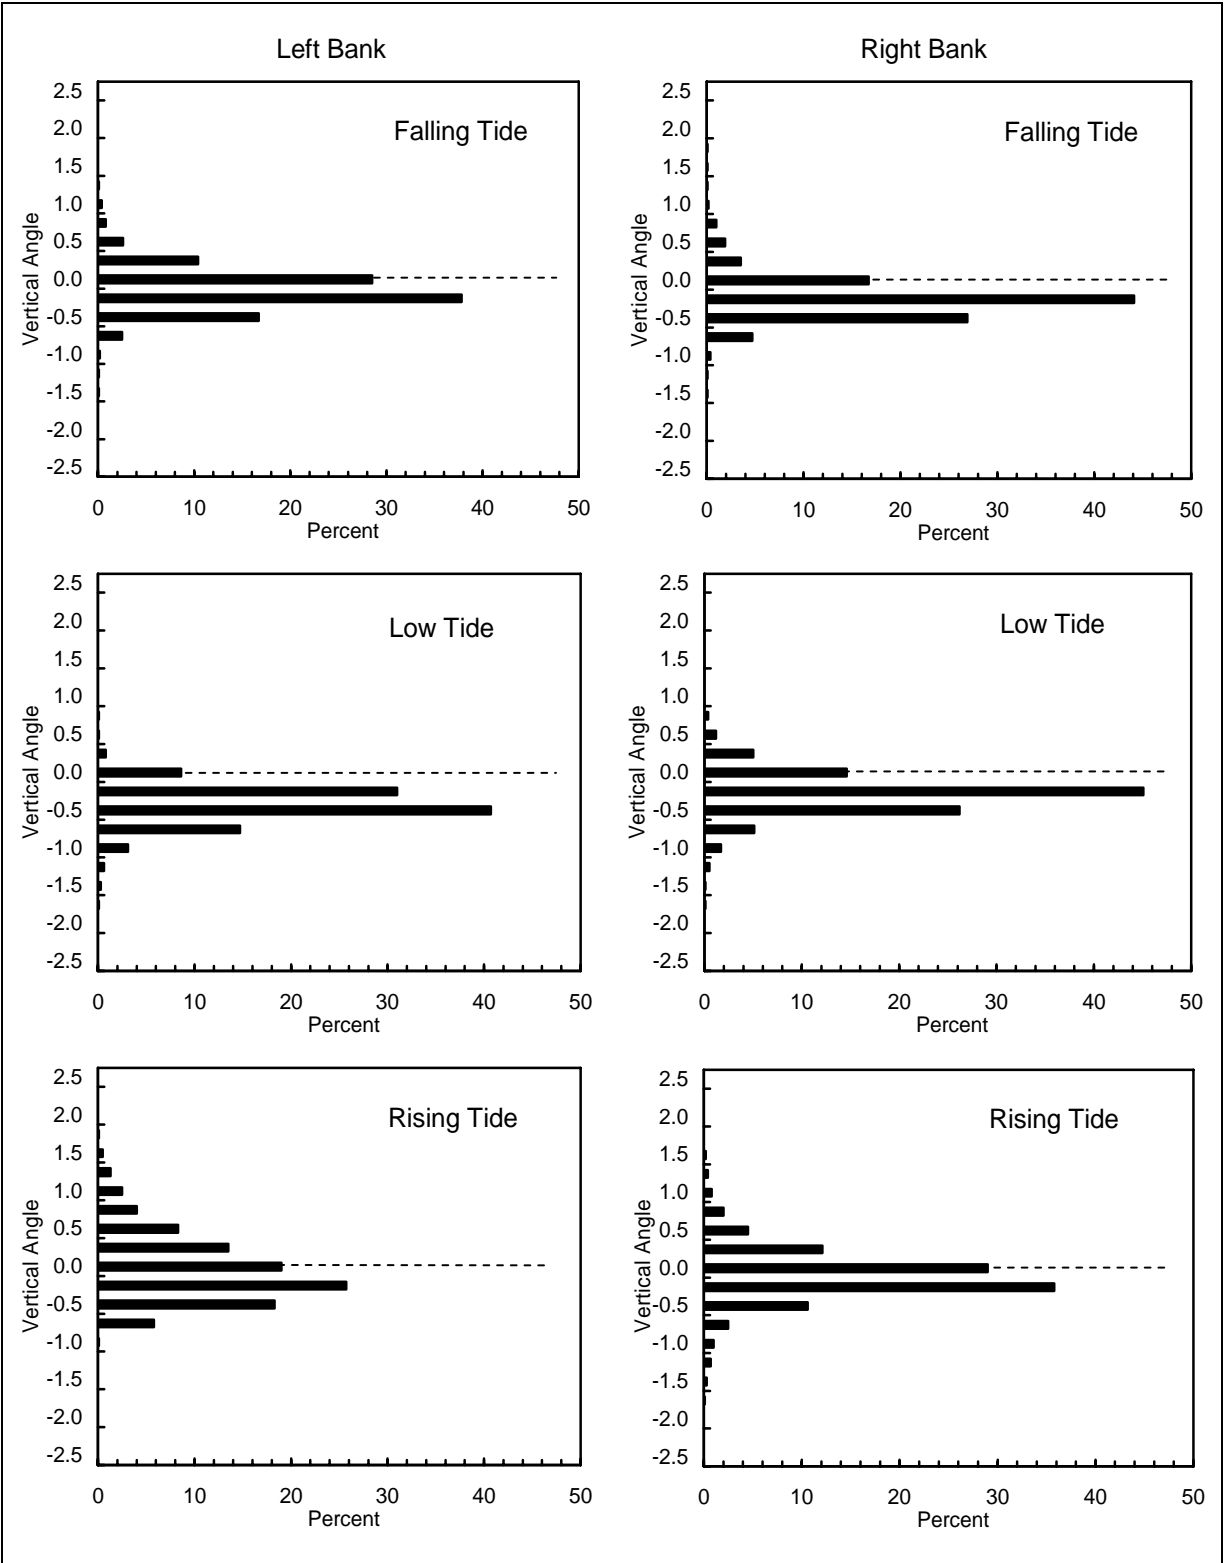

**Figure 10.**-Vertical distributions above and below the acoustic axis of late-run upstream and downstream moving Chinook salmon by bank, Kenai River, 2004.

## TARGET STRENGTH

Target strength distributions varied by bank, direction of travel, and run. Table 9 shows target strength statistics for fish that met minimum range and target strength criteria, whereas Figure 16 and Figure 17 show target strength distributions and statistics that include all tracked targets.

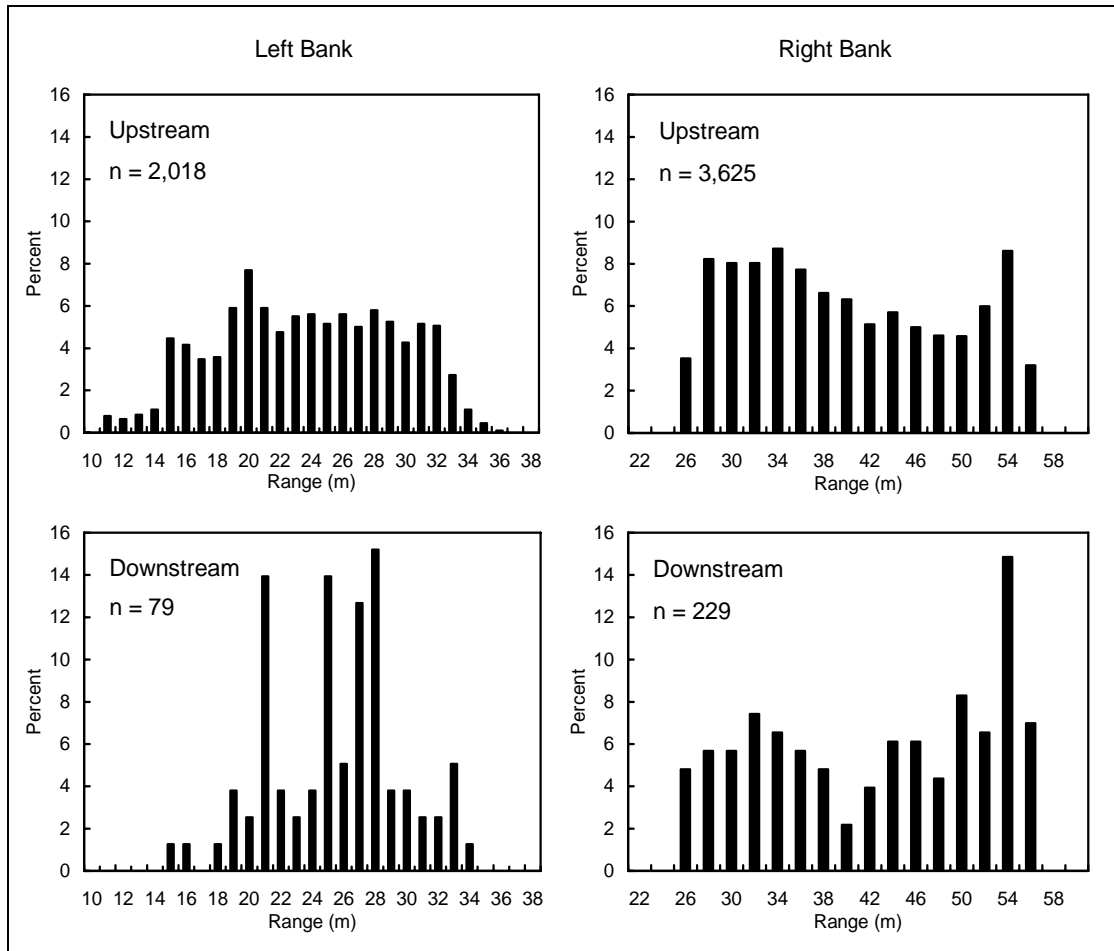

Mean target strength estimates for all upstream moving targets on the right bank during both the early and late run were 1 dB higher on average than left bank estimates (Figures 16 and 17). Mean target strength of all upstream and downstream moving targets varied more on the right bank than on the left bank.

During the early run on the left bank, mean target strength of Chinook salmon was similar ( $t = -1.01$ ,  $P = 0.16$ ) among upstream and downstream traveling fish, as was mean target strength variability ( $F = 1.07$ ,  $P = 0.31$ , Table 9). On the right bank, mean target strength of upstream

Note: Data have been filtered by range (distance from transducer) and target strength criteria. Acoustic axis = 0.0.

**Figure 11.**-Vertical distributions above and below the acoustic axis of late-run upstream moving Chinook salmon by tide stage and bank, Kenai River, 2004.

Note: Data have been filtered by range (distance from transducer) and target strength criteria.

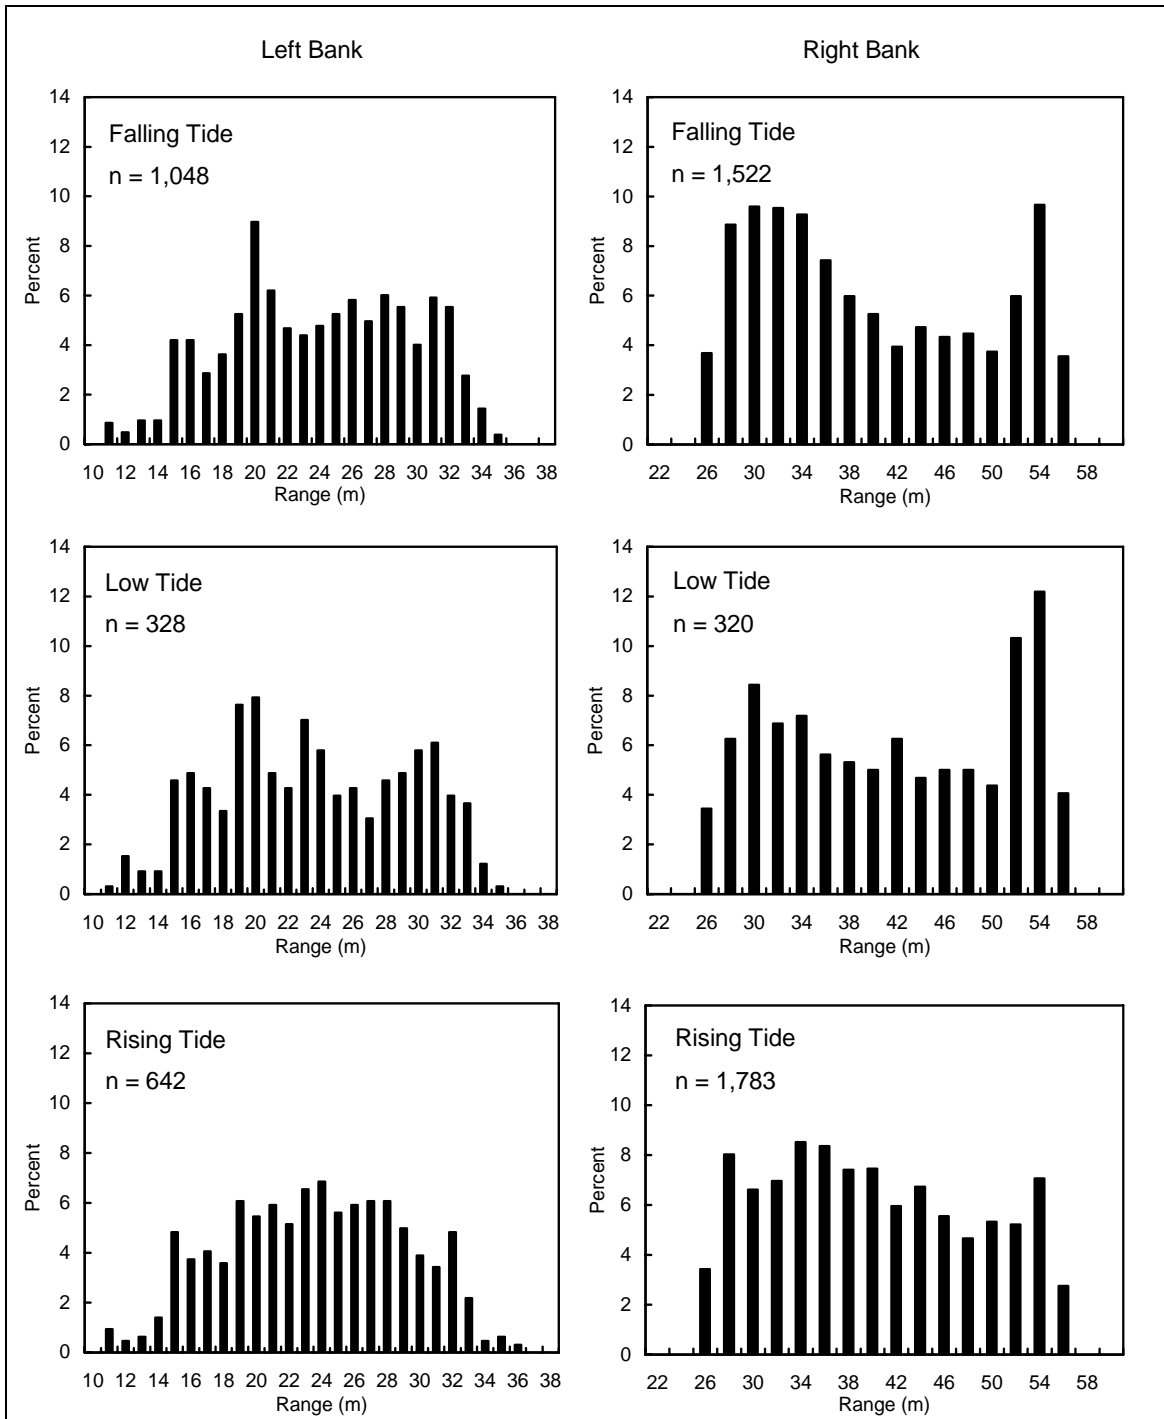

**Figure 12.**-Standardized distance from transducer of early-run upstream and downstream moving Chinook salmon by bank, Kenai River, 2004.

traveling Chinook was slightly higher ( $t = -4.96$ ,  $P < 0.01$ ), and variability was greater ( $F = 0.78$ ,  $P < 0.01$ ) than that of downstream traveling Chinook (Table 9). The statistical significance of the difference in mean target strength between upstream and downstream traveling fish was likely an artifact of disparity in sample size than an actual difference in mean target strength.

During the late run on the left bank, mean target strength of Chinook salmon was again similar ( $t = 1.40$ ,  $P = 0.08$ ) among upstream and downstream traveling fish, but variability was higher for downstream fish ( $F = 1.21$ ,  $P < 0.01$ , Table 9). On the right bank during the late run, mean target strength was similar ( $t = -1.49$ ,  $P = 0.07$ ) among upstream traveling fish, as was mean target strength variability ( $F = 0.93$ ,  $P = 0.10$ , Table 9).

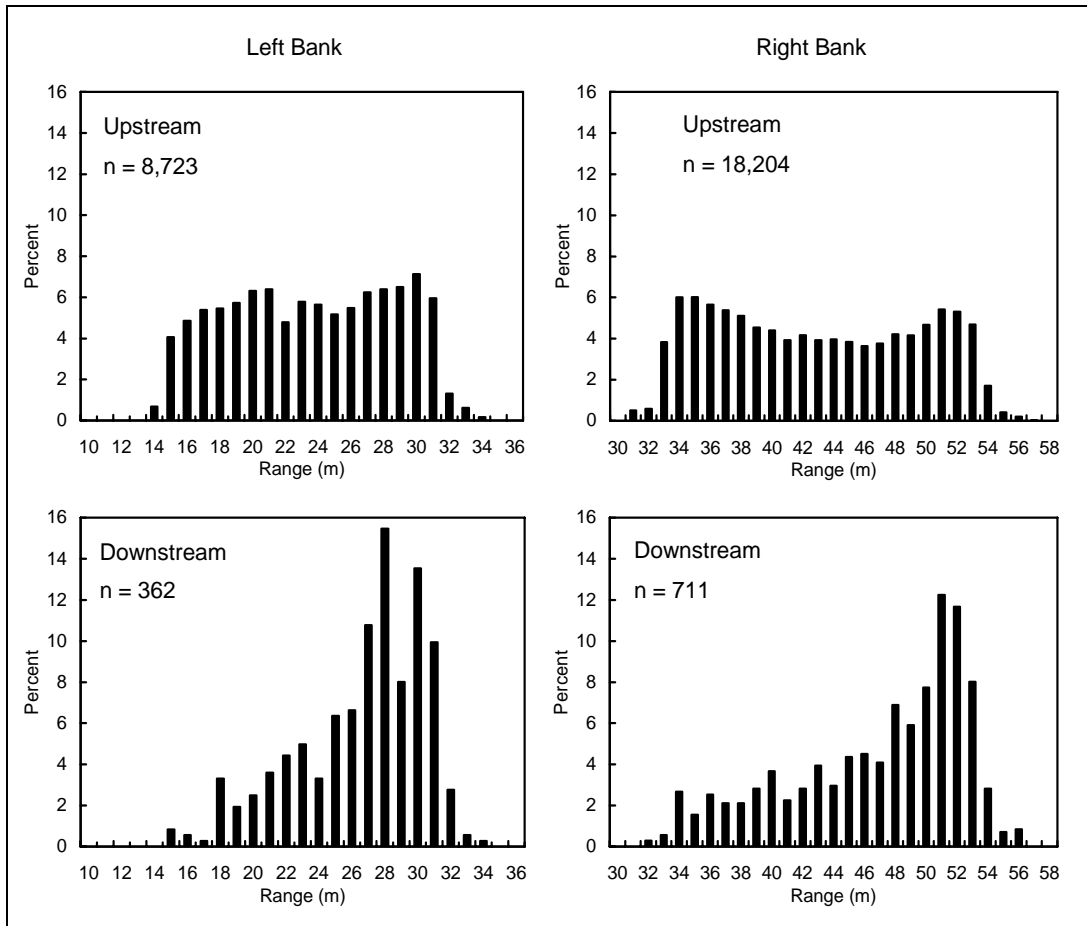

## PASSAGE ESTIMATES

Daily estimates of Chinook salmon passage were generated for 16 May through 5 August. A total of 546 hours of acoustic data were processed from the right bank and 617 hours from the left bank during the 82-day season. This represented 28% of available sample time (on average in a 24-hour period) for the right bank and 31% for the left bank.

Note: Data have been filtered by range (distance from transducer) and target strength criteria.

**Figure 13.**—Standardized distance from transducer of early-run upstream moving Chinook salmon by tide stage and bank, Kenai River, 2004.

Note: Data have been filtered by range (distance from transducer) and target strength criteria.

**Figure 14.** Standardized distance from transducer of late-run upstream and downstream moving Chinook salmon by bank, Kenai River, 2004.

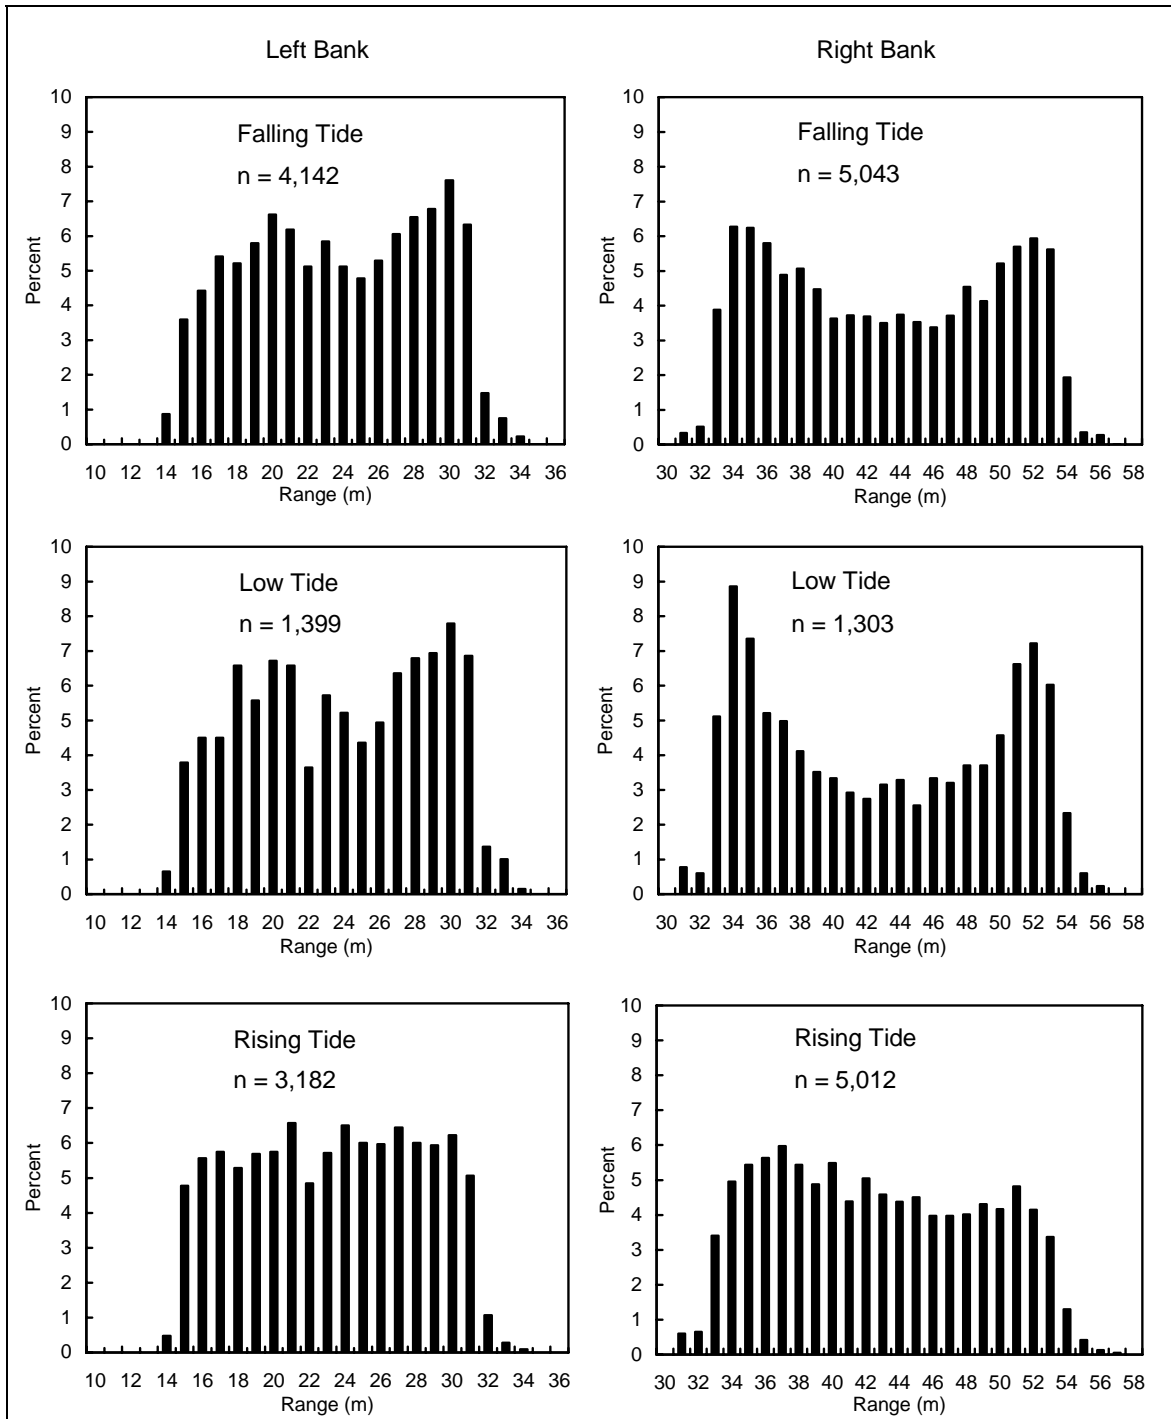

Final upstream Chinook salmon passage from 16 May to 5 August was estimated at 67,873 (SE = 641) fish, composed of 15,498 (SE = 261) early-run fish and 52,375 (SE = 585) late-run fish (Tables 7, 8, 10, and 11). Late-run passage extrapolated through 10 August was estimated at 56,205 (SE = 1,784) fish. The daily peak of the early run occurred on 10 June; 50% of the run passed by 14 June (Figure 18). When compared with historic mean escapement timing, the 2004 early run was late (Figure 18 and Appendix G1). The daily peak of the late run occurred on 16 July; 50% of the late run passed by 18 July (Figure 19). Migratory timing of the late run was average compared to historic mean escapement timing (Figure 19 and Appendix G2).

## DISCUSSION

### SPATIAL DISTRIBUTION

#### Bank Distribution

During the early years of the project (before 1996), the right bank was heavily used by migrating Chinook salmon during both the early and late runs, and the proportion of fish traveling up the right bank increased as the season progressed (Bosch and Burwen 1999; Burwen and Bosch 1998; 1995a; 1995b, 1996; Eggers et al. 1995; Miller and Burwen 2002). Since 1995 this trend has not been as obvious or as consistent. The 1996 and 1997 early runs experienced heavy

Note: Data have been filtered by range (distance from transducer) and target strength criteria.

**Figure 15.**—Standardized distance from transducer of late-run upstream moving Chinook salmon by tide stage and bank, Kenai River, 2004.

Total	52,375	100%	2,149	100%	54,524	100%

<sup>a</sup> Total passage (upstream component plus downstream component) is provided to maintain comparability between recent (1998-2004) fish passage estimates derived from split-beam sonar and composed of only upstream targets, and past estimates generated by split-beam (1995-1997) and dual-beam (1987-1994) sonar and composed of both upstream and downstream targets.

left-bank passage: almost half the upstream passage in the early run occurred on the left bank during both years (Bosch and Burwen 1999; Burwen and Bosch 1998). The 1999 and 2001 early and late runs both experienced a higher proportion of passage on the left bank than on the right bank (Miller and Burwen 2002; Miller et al. 2003). The left bank also had a higher proportion of passage during the early runs in 2002 and 2003 (Miller et al. 2004, 2005). In 2004, the majority of Chinook salmon passage during both runs occurred on the right bank (Tables 7 and 8). The differences in bank distribution do not appear to be related to changes in bottom contour, as the bottom profile at the site has remained relatively stable over the past several years. Bosch and Burwen 1999 pointed out that below average stream flows during the early runs of 1996 and 1997 might have influenced bank distribution. Below average stream flows also occurred in 1999 (Miller et al. 2002). However, flows from 2001 to 2003 were near or above average during both runs (Miller et al. 2003, 2004, 2005; USGS 2004). Thus, stream flows do not appear to fully account for changes in bank distribution.

**Table 9.** Mean target strength (dB) for upstream and downstream moving targets (Chinook salmon only) by riverbank during the early (16 May-30 June) and late (1 July-5 August) runs, 2004

Location	Upstream Mean			Downstream Mean

Right Bank	-25.72	1.74	18,204	-25.82	1.68	711

### Vertical Distribution

Monitoring the spatial distribution of migrating fish is particularly important at the present sonar site, where tide-induced changes in water level have been shown to affect fish distribution. A primary concern is that fish may swim over the beam during rising and falling tide stages. Because the site experiences extreme semidiurnal tidal fluctuations that average 4 m, and are as high as 7 m (Figure 3), it is not possible to insonify the entire cross-sectional area of the river. However, fish position data suggest that most upstream moving fish are within the insonified zone. When sockeye are not present in large numbers, most Chinook salmon are observed migrating offshore in the bottom portion of the river where beam coverage is maximized. Although more fish were in the upper half of the beam during rising tides on both banks during the 2004 early run (Figure 9), relatively few fish occupied the upper half of the beam overall (Figure 8). Similar trends occurred during the late run (Figures 10 and 11). Previous data show that fish in general have maintained a strong bottom orientation during all three tide stages during both the early and late runs (Burwen et al. 1995; Eggers et al. 1995).

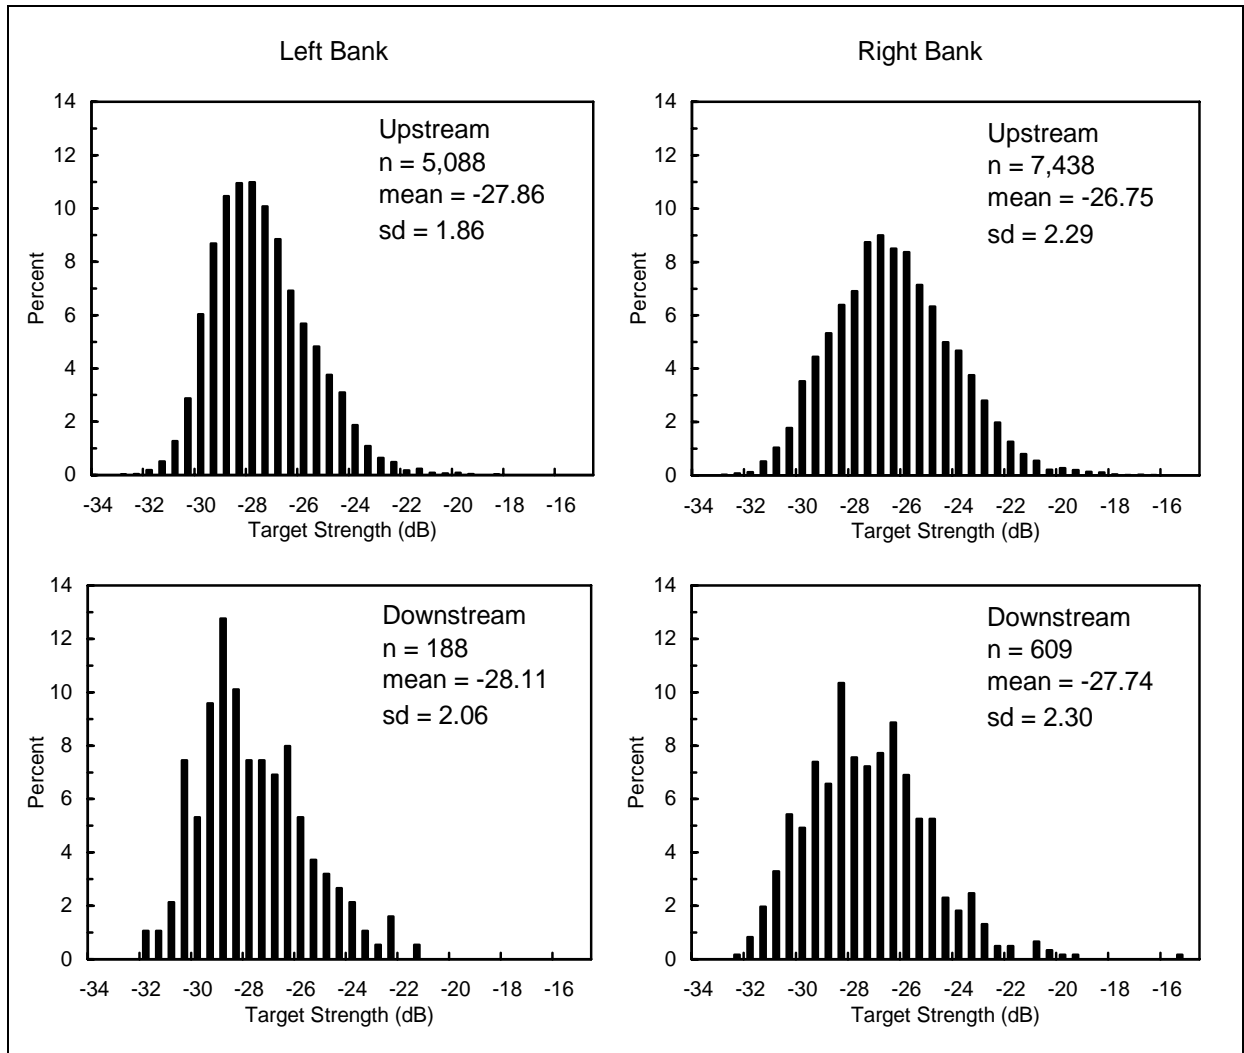

Because the vast majority of Chinook salmon travel close to the river bottom (Figures 8 and 10), our greatest concern is missing fish passing under the sonar beam. However, no fish were detected below beam angles of  $-2.0^\circ$  (Figures 8 and 10). Even with the reduced ability to detect targets on the edge of the “effective” beam, we assume there would be more targets detected if substantial numbers of fish were traveling in this area.

### Range Distribution

Because transducer locations varied throughout the season due to changing water levels (Figure 4), fish range distributions by bank and run were standardized based on the closest nearshore transducer. Hence, fish range distributions for a given bank reflect distance from the closest nearshore transducer location for that bank.

The range distribution of upstream traveling Chinook salmon on the left and right banks indicates that fish were dispersed throughout the insonified range during both the early and late run (Figures 12 and 14). The truncated distribution of fish targets on the left bank (from 15 to 31 m for the early run, and from 15 to 32 m for the late run) is an artifact of target filtering and

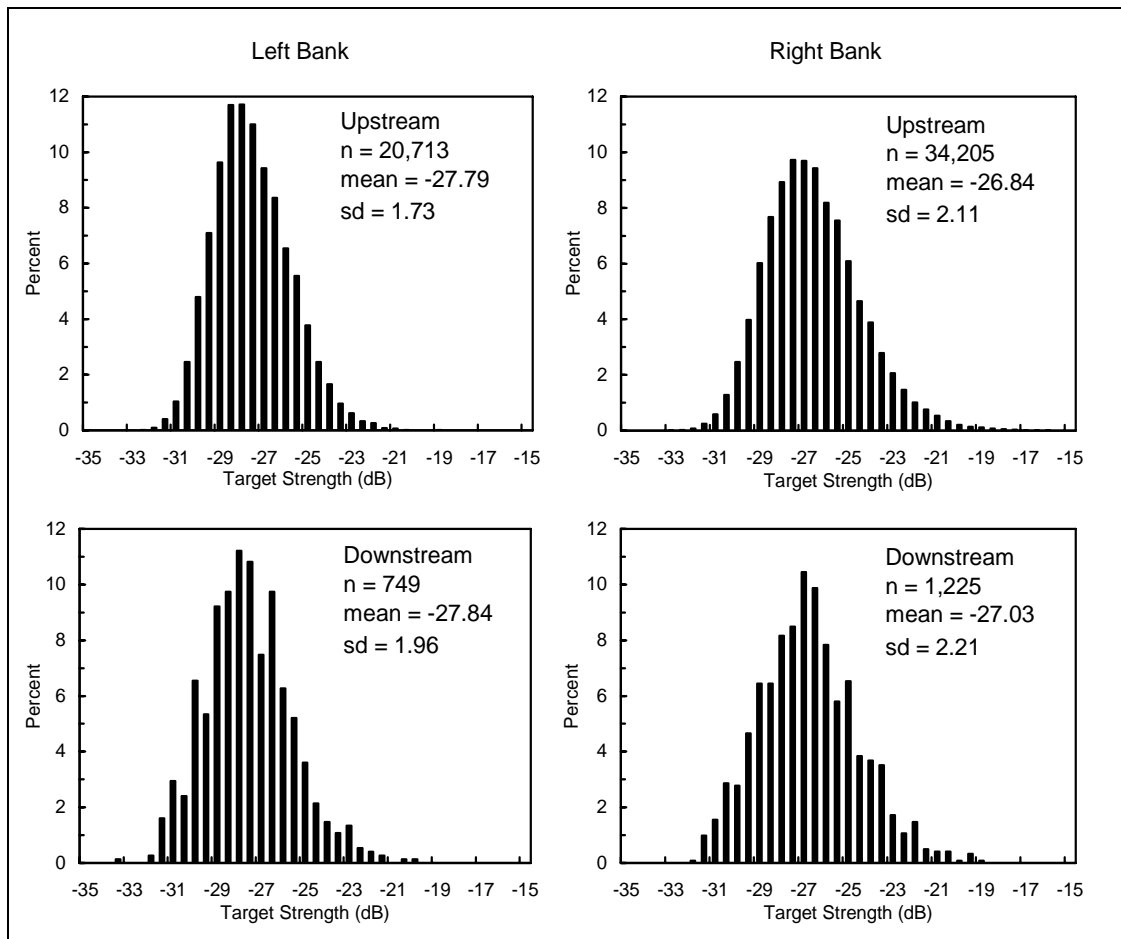

Note: Data have not been filtered by range (distance from transducer) and target strength criteria.

**Figure 16.**-Early-run target strength (acoustic size) for all upstream and downstream moving targets by bank, Kenai River, 2004.

transducer relocations. The truncated distribution of fish targets on the right bank (from 26 to 53 m for the early run, and from 31 to 54 m for the late run) is also an artifact of target filtering and transducer relocations.

## TARGET STRENGTH

From 1996 to 2000, mean target strength estimates on the left bank were higher on average than the right bank (6% higher for early run; 9% higher for later run; Bosch and Burwen 1999; 2000; Burwen and Bosch 1998; Miller and Burwen 2002; Miller et al. 2002). The higher mean target strength observed on the left bank was attributed to threshold-induced bias rather than actual differences in fish size. It was concluded that the acoustically reflective gravel substrate prevented the sonar beam from being aimed as close to the river bottom on the left bank as it was

Note: Data have been filtered by range (distance from transducer) and target strength criteria.

**Figure 17.**-Late-run target strength (acoustic size) for all upstream and downstream moving targets by bank, Kenai River, 2004.

on the right. Because left-bank fish were, on average, farther from the acoustic axis than right-bank fish, a greater proportion of small echoes from left-bank fish were filtered out, thus biasing target strength estimates upward. In addition, the higher background noise experienced on the left bank resulted in higher variability in positional estimates, which also resulted in a positive target strength bias (Fleischman and Burwen 2000).

In 2001 and 2002, mean target strength estimates were very similar between the left and right bank during both the early and late run (Miller et al. 2003, 2004). The similarity in mean target strength between banks was attributed to the relocation of the left-bank transducer in 2001 and the improved left-bank aim that provided more on-axis targets. Since 2002, mean target strength estimates during both runs have been slightly higher on the right bank than on the left bank (Miller et al. 2005; Figures 16 and 17).

## ACCURACY OF ABUNDANCE ESTIMATES

Past research indicates that sonar estimates of Chinook passage are subject to potential bias from several sources including: (1) imperfect target detection (fish swimming above, below, or

<sup>a</sup> Counting operations were terminated on 5 August. Daily passage for 6-10 August was estimated using total passage through 5 August and the mean proportion of passage from 6-10 August for years 1987-88, 1990, 1992-93, 1995, and 1998-2001.

Note: Mean in bottom panel is based on estimates of total passage for 1988-1997 and upstream passage for 1998-2003.

**Figure 18.**-Daily sonar passage estimates by bank (top), total passage (center), and historical cumulative proportions (bottom) for the early run of Chinook salmon returning to the Kenai River, 2004.

Note: Mean in bottom panel is based on passage through 5 August and on estimates of total passage for 1987-1997 and upstream passage for 1998-2003.

behind the effective beam; or not meeting the voltage threshold), (2) errors in target tracking (including direction of travel), and (3) inaccurate species discrimination. Bias from the first two sources would generally be small, consistent, or negative (resulting in conservative estimates). We are more concerned about species discrimination errors, which can cause large biases (in either direction).

Our current species discrimination algorithm, based on target strength and range thresholds, is less than satisfactory. Target strength is an imprecise predictor of fish size and species; many sockeye salmon exceed the  $-28$  dB target strength threshold and many Chinook salmon do not (Burwen and Fleischman 1998). And although only a small fraction of sockeye salmon swim outside of our range thresholds, they can comprise more than 50% of fish in mid-channel (Burwen et al. 1998). Under these circumstances range thresholds are ineffective, and Chinook abundance can be overestimated. In response, we refined our species discrimination algorithm in 2000. Fish distribution and behavior made it evident when sockeye were abundant in mid-river; episodes of abundant sockeye in mid-river were often discrete and short-lived. Since 2000, when we suspected that this occurred, we have censored the data from the associated 1-hour samples, and generated the abundance estimate from the remaining hourly samples (see Methods). This procedure has reduced the probability of grossly overestimating Chinook abundance, but it has the drawback of being somewhat subjective to implement, and it may increase the probability of underestimating abundance. Inclusion of all available hourly samples in 2004, regardless of the presence of offshore sockeye, would have generated a late-run Chinook passage estimate through 5 August of 81,359 (SE = 1,520). However, this estimate is likely biased high, and under normal circumstances (i.e., no censoring of samples) would have been lower because of the extension of range thresholds to compensate for the large numbers of sockeye present in mid-river.

We are developing two alternative methods of estimating the species composition for the inriver return based on: (1) catches in the drift gillnets, and (2) echo length (“pulse width”) measurements, analyzed with a mixture model. The first alternative method (see Methods and Reimer *In prep*) uses data from gillnets drifted immediately below the sonar site to estimate the species composition of fish counted by the sonar. The second alternative method (Appendix I) is based on echo length standard deviation (ELSD), which is a better hydroacoustic index of fish size than target strength (Burwen et al. 2003). Both methods offer the advantage of objective species discrimination and the means to assess the associated uncertainty. Although these alternative methods are experimental, we are hopeful that they will lead to more accurate estimates of Chinook salmon passage. At present, we compare the alternative methods with the “standard” method to help gauge their accuracy.

Historically, we have also compared sonar estimates of Chinook abundance with several other indices of Chinook and sockeye abundance to aid in evaluating the sonar’s accuracy. These indices include CPUE from gillnets drifted at the sonar site, Chinook CPUE in the sport fishery, and daily estimates of sockeye salmon at the river mile-19 sonar site.

Gillnets have been drifted near the sonar site since the 1980s to estimate age composition (Reimer et al. 2002). In 1998, gillnetting methods were standardized to produce consistent estimates of CPUE, which we hoped to compare within and between years as an index of Chinook salmon abundance. After analyzing the 1998-2000 standardized data, we concluded that gillnet CPUE is, at best, an inconsistent index of abundance, because it is highly variable and is affected by river discharge and water clarity. Several changes to the gillnetting procedures were implemented in 2002: an additional mesh size (5”) was added, nets were constructed of

multi-monofilament (formerly cable-lay braided nylon), the color of the mesh was changed to more closely match that of the river, and drifts were shortened and constrained to more closely match the portion of the channel sampled by the sonar. These changes increased netting efficiency, and decreased the effect of water clarity on gillnet catches (Reimer 2004a).

Inriver sport fish CPUE, estimated with an intensive creel survey (Reimer *In prep*), has historically been considered a useful index of Chinook salmon abundance. Recent observations indicate that this index has little or no predictive value, even after controlling for the effects of water clarity and discharge. However, we continue to present sport fish CPUE (Figures 20 and 21) for historical consistency.

The river mile-19 sockeye sonar site, located upriver of the Chinook sonar site, provides an index of inriver sockeye salmon abundance. This sonar project is conducted from 1 July to mid August by the Commercial Fisheries Division and targets sockeye salmon near shore (Westerman and Willette 2003). Although travel time between the river mile-8.6 Chinook sonar site and the river mile-19 sockeye sonar site varies, we believe it averages 1 to 2 days. This project identifies periods when sockeye are abundant and when the potential for misclassifying sockeye as Chinook salmon may be high.

### **Early Run**

The 2004 early-run standard sonar passage estimate of 15,498 Chinook salmon was average to above average (Appendix G1). A large eulachon *Thaleichthys pacificus* migration in late May and early June resulted in sound shadowing effects that forced us to exclude the most severely affected hourly samples from calculation of the early-run daily passage estimate. Approximately 4% of the early run sample hours were dropped because of the sound shadowing effects. It is possible late-May and early-June passage estimates were biased low as a result of these actions.

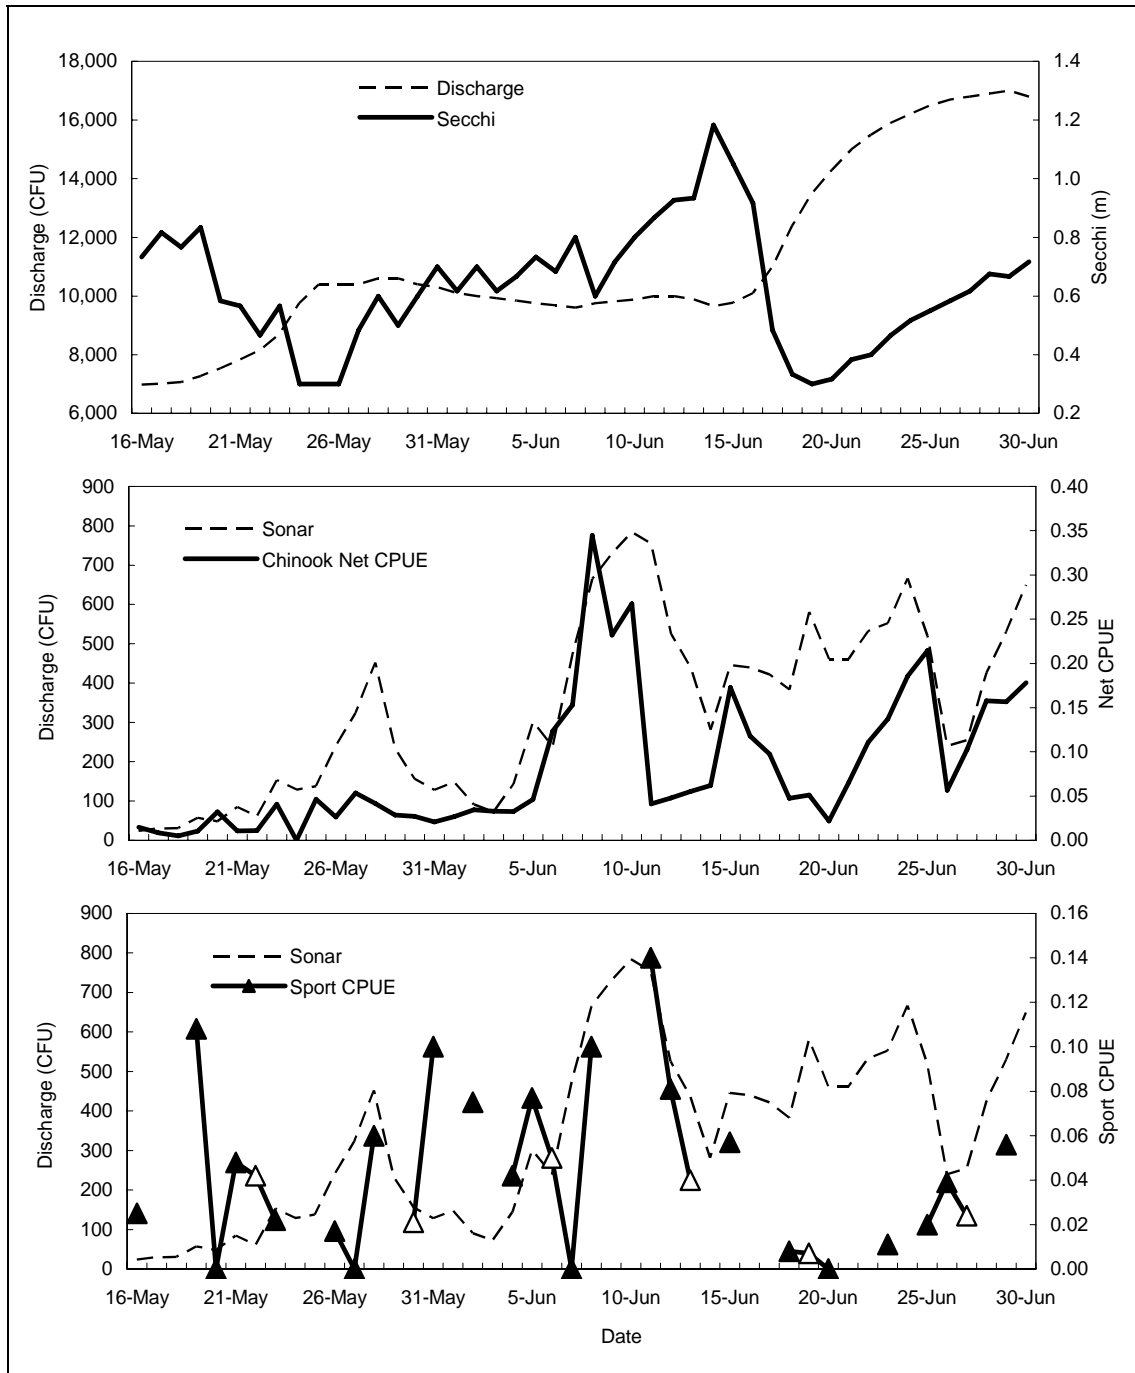

Net-apportioned estimates, which are the product of unfiltered sonar estimates and the proportion of Chinook salmon in the gillnet catches (Equation 12), tracked standard sonar estimates fairly well and totaled 17,998 (SE = 710), which was 16% higher than the standard early-run estimate of 15,498 (Figure 22; Appendix H1). The standard estimates generally exceeded the net-apportioned estimates through 6 June, but were lower throughout much of the remaining early run.

The ELSD mixture model estimated 17,264 (SE = 707) Chinook salmon in the early run, approximately 11% higher than the standard sonar estimate (Appendix I). The standard sonar and mixture model estimates were close during the first 6 weeks of the early run, with standard sonar estimates falling within the 95% mixture model confidence intervals for 5 of the 6 weeks. During the seventh and final week, however, the mixture model estimate was substantially higher than the standard sonar estimate (Figure I1.4).

Mixture and net-apportioned abundance estimates tracked fairly well (Figure I1.4). Ninety-five percent confidence interval estimates overlapped for all weeks. Similar observations were made during the 2002 and 2003 early runs (Miller et al. 2004, 2005). We are encouraged that the two estimates, which are largely independent of each other, are correlated (Figure I1.5). In 2004, both tracked well with the standard sonar estimate. All three estimates indicate an average to slightly above average run in 2004.

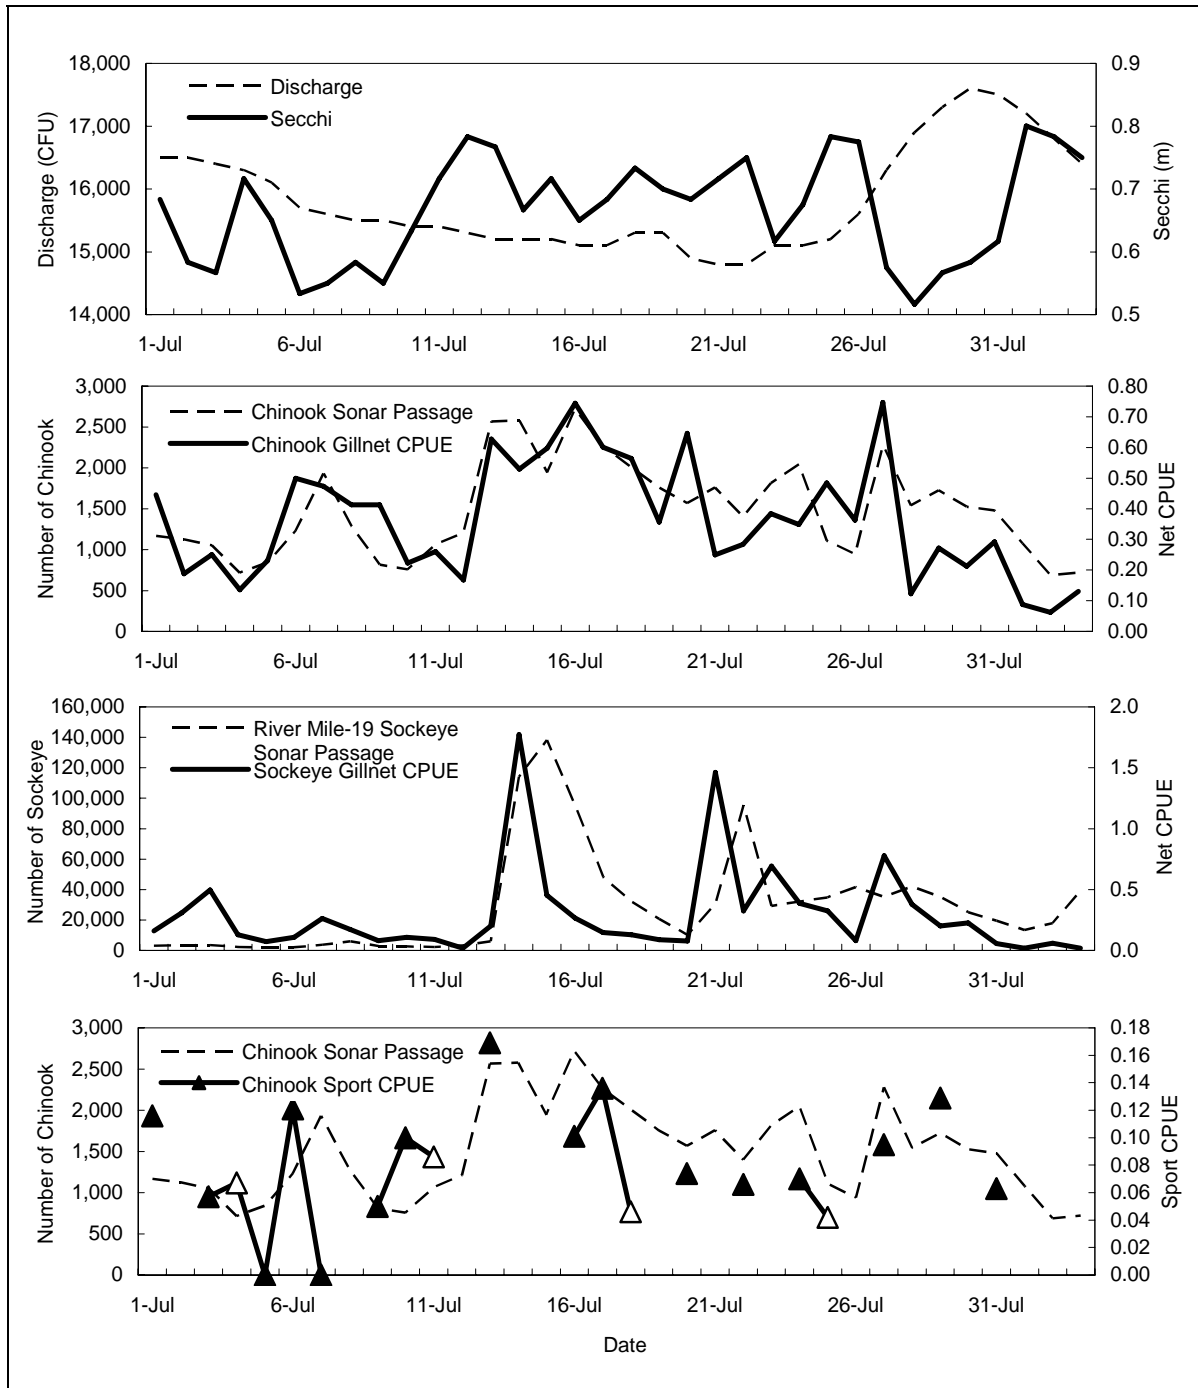

As in past years (Reimer et al. 2002) sonar estimates and gillnet CPUE tracked each other short-term, but the relationship changed over time (Figure 20). Peaks in estimated sonar passage

Note: Net CPUE and sport fish CPUE taken from Reimer (*In prep*). Open triangles represent days on which only unguided anglers were allowed to fish.

**Figure 20.**-Daily discharge rates collected at the Soldotna Bridge, Secchi disk readings taken in front of the sonar site, Chinook sonar passage estimates, inriver gillnet CPUE, and Chinook sport fish CPUE, early run (16 May-30 June), Kenai River, 2004.

Note: River mile-19 sockeye sonar estimates taken from Westerman and Willette (2006). Net CPUE and sport fish CPUE taken from Reimer (*In prep*). The Chinook sport fishery closed by regulation on 31 July, so no sport fish CPUE data were available after this date. Open triangles represent days when only unguided anglers were allowed to fish.

**Figure 21.**-Daily discharge rates collected at the Soldotna Bridge, Secchi disk readings taken in front of the sonar site, Chinook sonar passage estimates, inriver gillnet CPUE, river mile-19 sockeye sonar passage estimates, and Chinook sport fish CPUE, late run (1 July-5 August), Kenai River, 2004.

**Figure 22.**—Estimated early- (top) and late-run (bottom) fish passage based on unfiltered sonar (all species), standard filtered sonar (Chinook only), and net-apportioned sonar (alternative estimate, Chinook only), Kenai River, 2004.

and gillnet CPUE generally were aligned, but the relative magnitude of the changes in the two estimates varied through time. For instance, CPUE was particularly low relative to the sonar estimate on 26-30 May, 9-14 June, and 17-24 June (Figure 20). Gillnet CPUE on 17-24 June may have been influenced by the rapid fluctuations in discharge and water clarity observed. A similar disparity occurred during this time between sonar estimates and Chinook sport fish CPUE (Figure 20).

### Late Run

The 2004 late-run standard sonar passage estimate through 5 August of 52,375 Chinook salmon was above average (Appendix G2). Net-apportioned sonar estimates tracked the standard sonar estimates well, but were consistently higher than the standard sonar estimates throughout much of the late run (Figure 22; Appendix H2). The cumulative net-apportioned estimate of 75,049 (SE = 2,679) Chinook salmon was 43% higher than the standard sonar estimate. A similar percentage was observed during the 2003 late run (Miller et al. 2005). The higher net-apportioned estimate in 2003 was partially attributed to the higher than average proportion of

small Chinook salmon caught in gillnets that year. The proportion of small Chinook salmon caught in gillnets during the 2004 late run (Reimer *In prep*) was less than half the proportion caught during the 2003 late run (Reimer 2004b).

Based on sockeye salmon gillnet CPUE and river mile-19 sockeye salmon sonar estimates (Figure 21), substantial numbers of sockeye salmon were present at the Chinook sonar site throughout much of July. Peak Chinook sonar passage, however, did not always coincide with peak sockeye salmon gillnet CPUE. On days when it did coincide, the magnitude of the increase in estimated Chinook passage was small relative to the increase in sockeye gillnet CPUE. In fact, several estimated peaks of Chinook salmon passage occurred on days with relatively low sockeye salmon gillnet CPUE (Figure 21). If significant misclassification of sockeye occurred, we would expect it to have occurred on days of peak sockeye salmon gillnet CPUE.

Throughout most of the late run, Chinook gillnet CPUE tracked fairly well with the daily sonar estimates (Figure 21). Some exceptions occurred on days when increases in gillnet CPUE corresponded with decreases in daily sonar estimates (and vice versa), but the magnitude of the increases or decreases were relatively small.

In summary, misclassification of sockeye salmon as Chinook salmon was likely minimal in 2004, and comparison of the standard estimate with the alternative net-apportioned estimate suggests that the late-run standard estimate may have been conservatively low (i.e., underestimated Chinook abundance).

## **OUTLOOK**

We continue to pursue several avenues of investigation for improving our estimates of Chinook salmon abundance. Refinements made to the gillnetting project in 2002 have resulted in improved net-apportioned estimates, and we plan to continue to use them experimentally as an objective alternative index of Chinook abundance. Likewise, ELSD mixture model estimates have proven useful during the early run when sockeye salmon density is low. We are developing estimates of gillnet size-selectivity to correct both alternative estimates in 2004 and to further investigate the feasibility of implementing mixture model estimates for the late run.

It is possible that current echo length measurements can be improved to provide more precise estimates of fish size. An Alaska Sea Grant has been awarded to fund a graduate student at the University of Washington starting in September 2006. This student will focus on developing methods to improve the relationship between echo pulse shape and fish size.

Finally, we will continue experiments in 2005 using DIDSON imaging sonar to produce camera-quality images of fish up to 15 m and determine reasonably accurate measurements of fish size. In 2005, a DIDSON imaging system will be run simultaneously with an independent split-beam sonar system. The goal of this research is to synchronize split-beam and DIDSON data on free-swimming Chinook and sockeye salmon. If a sufficient sample size for each species is obtained, then species classification techniques can be tested on free-swimming fish of known size and species for the first time.

## **ACKNOWLEDGMENTS**

We would like to thank Mark Jensen for his assistance in overseeing the day-to-day operation of the project, for providing computer programming and networking support, and for his assistance in reducing and analyzing the data. We would also like to thank Linda Lowder, Mike Hopp, Don Eide, and Jenny Cope for meticulously collecting the sonar data and for their high level of

motivation throughout a long field season. We would like to express our gratitude to Brian Lowe for allowing us to use his dock for project deployment and breakdown. Special thanks, also, to Division of Sport Fish staff in Soldotna who provided logistical support during project deployment and breakdown, and when needed throughout the season.

## **APPENDIX A. TARGET STRENGTH ESTIMATION**

**Appendix A1.**-The sonar equation used to estimate target strength (dB) with dual- and split-beam applications.

---

Target strength (TS), in decibels (dB), of an acoustic target located at range  $R$  (in m),  $\theta$  degrees from the maximum response axis (MRA) in one plane and  $\phi$  degrees from the MRA in the other plane is estimated as:

$$TS = 20 \log_{10}(V_o) - SL - G_r + 40 \log_{10}(R) + 2\alpha R - G_{TVG} - 2B(\theta, \phi),$$

where:

$V_o$  = voltage of the returned echo, output by the echo sounder;

$SL$  = source level of transmitted signal in dB;

$G_r$  = receiver gain in dB;

$40\log_{10}(R)$  = two-way spherical spreading loss in dB;

$2\alpha R$  = two-way absorption loss in dB;

$G_{TVG}$  = time-varied-gain correction of the echo sounder; and

$2B(\theta, \phi)$  = two-way loss due to position of the target off of the MRA.

The source level and gain are measured during calibration and confirmed using *in situ* standard sphere measurements. The time-varied-gain correction compensates for spherical spreading loss. Absorption loss ( $2\alpha R$ ) was ignored in this study.

In practice, the location of the target in the beam ( $\theta$  and  $\phi$ ) is not known, so  $B(\theta, \phi)$  must be estimated in order to estimate target strength. Dual-beam and split-beam sonar differ in how they estimate  $B(\theta, \phi)$ , also called the beam pattern factor.

Dual-beam sonar (Ehrenberg 1983) uses one wide and one narrow beam. The system transmits on the narrow beam only and receives on both. The ratio between the voltages of the received signals is used to estimate beam pattern factor:

$$B(\theta, \phi) = 20 \log(V_N/V_W) \bullet WBDO,$$

where  $V_N$  is the voltage of the returned echo on the narrow beam,  $V_W$  is the voltage of the echo on the wide beam, WBDO is the wide beam drop-off correction, specific to each transducer, and estimated at calibration.

Split-beam sonar (MacLennan and Simmonds 1992) estimates target location (angles  $\theta$  and  $\phi$  of the target from the MRA) directly, not just the beam pattern factor ( $B(\theta, \phi)$ ). Split-beam transducers are divided into four quadrants, and  $\theta$  and  $\phi$  are estimated by comparing the phases of signals received by opposing pairs of adjacent quadrants. The beam pattern factor is a function of  $\theta$  and  $\phi$ , determined during laboratory calibration.

---

## **APPENDIX B. SYSTEM PARAMETERS**

**Appendix B1.**-Example of system parameters used for data collection on the right bank (transducer 733).

\* Start Processing at Port 1 -FILE\_PARAMETERS- Thursday July 1 12:00:09 2004

\* Data processing parameters used in collecting this file for Port 1

100	-1	1	MUX argument #1 - multiplexer port to activate
101	-1	0	percent - sync pulse switch, ping rate determiner NUS
102	-1	13201	maxp - maximum number of pings in a block NUS
103	-1	32767	maxbott - maximum bottom range in samples NUS
104	-1	13	N_th_layer - number of threshold layers
105	-1	5	max_tbp - maximum time between pings in pings
106	-1	5	min_pings - minimum number of pings per fish
507	-1	FED5	timval - 0xFED5 corresponds to about 20 kHz NUS
108	-1	1	mux_on - means multiplexing enabled on board NUS
109	-1	200	mux_delay - samples delay between sync and switching NUS
110	-1	0	decimate_mask - decimate input samples flag NUS
112	-1	1	echogram_on - flag for DEP echogram enable 0=off, 1=on
113	-1	1	Hourly Sampling flag 1=On 0=Off
118	-1	5	maxmiss - maximum number of missed pings in auto bottom
119	-1	0	bottom-0=fix,1=man,2=scope,3=acq_chan1,4=acq_chan2,5=auto_1,6=auto_chan2
120	-1	0	sb_int_code - sb only=0, sb-int: 40log a bot=1, 20log=2
121	-1	0	sb_int_code2 - sb only=0, sb-int 40log eg=0, 20log=2
122	-1	13	N_int_layers-number of integration strata
123	-1	13	N_int_th_layers - number of integration threshold strata
124	-1	0	int_print - print integrator interval results to printer
125	-1	0	circular element transducer flag for bpf calculation
126	-1	80	grid spacing for Model 404 DCR (in samples, 16 s/m)
127	-1	1	TRIG argument #1 - trigger source
128	-1	0	TRIG argument #2 - digital data routing
130	-1	0	TVG Blank (0=Both Start/End,1=Stop Only,2=Start Only,3=None)
200	-1	20	sigma flag 0.0 = no sigma, else sigma is output
201	-1	220.57	sl - transducer source level
202	-1	-170.51	gn - transducer through system gain at one meter
203	-1	-18	rg - receiver gain used to collect data
204	-1	2.8	narr_ax_bw - vertical nominal beam width
205	-1	10	wide_ax_bw - horizontal axis nominal beam width
206	-1	0	narr_ax_corr - vertical axis phase correction
207	-1	0	wide_ax_corr - horizontal axis phase correction
208	-1	11.0011	ping_rate - pulses per second
209	-1	0	echogram start range in meters
210	-1	38	echogram stop range in meters
211	-1	713	echogram threshold in millivolts
212	-1	13.2	print width in inches
213	-1	0	Chirp Bandwidth (0.0 = CHIRP OFF)
214	-1	20	Sampling within Hour Ending Time (in Decimal Minutes)
215	-1	1500	Speed of Sound (m/s)
216	-1	200	The Transducer's Frequency (kHz)
217	-1	-2.5	min_angoff_v - minimum angle off axis vertical
218	-1	2	max_angoff_v - maximum angle off axis vertical
219	-1	-5	min_angoff_h - minimum angle off axis horiz.

-continued-

## Appendix B1.-Page 2 of 3.

220	-1	5	max_angoff_h - maximum angle off axis horiz.
221	-1	-24	max_dB_off - maximum angle off in dB
222	-1	-15.9377	ux - horizontal electrical to mechanical angle ratio
223	-1	-31.4935	uy - vertical electrical to mechanical angle ratio
224	-1	0	ud_coef_a - a coeff. for up-down beam pattern eq.
225	-1	-0.0019	ud_coef_b - b coeff. for up-down beam pattern eq.
226	-1	-2.5744	ud_coef_c - c coeff. for up-down beam pattern eq.
227	-1	0.0563	ud_coef_d - d coeff. for up-down beam pattern eq.
228	-1	-0.1206	ud_coef_e - e coeff. for up-down beam pattern eq.
229	-1	0	lr_coef_a - a coeff. for left-rt beam pattern eq.
230	-1	-0.0007	lr_coef_b - b coeff. for left-rt beam pattern eq.
231	-1	-0.211	lr_coef_c - c coeff. for left-rt beam pattern eq.
232	-1	0.001	lr_coef_d - d coeff. for left-rt beam pattern eq.
233	-1	-0.0002	lr_coef_e - e coeff. for left-rt beam pattern eq.
234	-1	4	maximum fish velocity in meters per second
235	-1	1	Echo Scope Bottom Location
236	-1	0.4	maxpw - pulse width search window size
238	-1	35.5	bottom - bottom depth in meters
239	-1	0	init_slope - initial slope for tracking in m/ping
240	-1	0.2	exp_cont - exponent for expanding tracking window
241	-1	0.2	max_ch_rng - maximum change in range in m/ping
242	-1	0.04	pw_criteria->min_pw_6-min -6 dB pulse width
243	-1	10	pw_criteria->max_pw_6-max -6 dB pulse width
244	-1	0.04	pw_criteria->min_pw_12 - min -12 dB pulse width
245	-1	10	pw_criteria->max_pw_12 - max -12 dB pulse width
246	-1	0.04	pw_criteria->min_pw_18 - min -18 dB pulse width
247	-1	10	pw_criteria->max_pw_18 - max -18 dB pulse width
249	-1	10	maximum voltage to allow in .RAW file
250	-1	0.2	TX argument #1 - pulse width in milliseconds
251	-1	25	TX argument #2 - transmit power in dB-watts
252	-1	-12	RX argument #1 - receiver gain
253	-1	90.9	REP argument #1 - ping rate in ms per ping
254	-1	10	REP argument #2 - pulsed cal tone separation
255	-1	1	TVG argument #1 - TVG start range in meters
256	-1	100	TVG argument #2 - TVG end range in meters
257	-1	40	TVG argument #3 - TVG function (XX Log Range)
258	-1	-6	TVG argument #4 - TVG gain
259	-1	0	TVG argument #5 - alpha (spreading loss) in dB/Km
260	-1	0.2	minimum absolute distance fish must travel in x plane
261	-1	0.2	minimum absolute distance fish must travel in y plane
262	-1	0.2	minimum absolute distance fish must travel in z plane
263	-1	2	bottom_window - auto tracking bottom window (m)
264	-1	3	bottom_threshold - auto tracking bottom threshold (V)
265	-1	11.2	TVG argument #7 - 20/40 log crossover (meters)
266	-1	0	rotator - which rotator to aim
267	-1	0	aim_pan - transducer aiming angle in pan (x, lf/rt)
268	-1	0	aim_tilt - transducer aiming angle in tilt (y, u/d)
401	0	1	th_layer[0] - bottom of first threshold layer (m)
401	1	5	th_layer[1] - bottom of second threshold layer (m)

-continued-

## Appendix B1.-Page 3 of 3.

401	2	10	th_layer[2] – bottom of third threshold layer (m)
401	3	15	th_layer[3] – bottom of fourth threshold layer (m)
401	4	20	th_layer[4] – bottom of fifth threshold layer (m)
401	5	25	th_layer[5] – bottom of sixth threshold layer (m)
401	6	30	th_layer[6] – bottom of seventh threshold layer (m)
401	7	35	th_layer[7] – bottom of eighth threshold layer (m)
401	8	40	th_layer[8] – bottom of ninth threshold layer (m)
401	9	45	th_layer[9] – bottom of tenth threshold layer (m)
401	10	50	th_layer[10] – bottom of eleventh threshold layer (m)
401	11	55	th_layer[11] – bottom of twelfth threshold layer (m)
401	12	60	th_layer[12] – bottom of thirteenth threshold layer (m)
402	0	713	th_val[0], threshold for 1 <sup>st</sup> layer in millivolts
402	1	713	th_val[1], threshold for 2 <sup>nd</sup> layer in millivolts
402	2	713	th_val[2], threshold for 3 <sup>rd</sup> layer in millivolts
402	3	713	th_val[3], threshold for 4 <sup>th</sup> layer in millivolts
402	4	713	th_val[4], threshold for 5 <sup>th</sup> layer in millivolts
402	5	713	th_val[5], threshold for 6 <sup>th</sup> layer in millivolts
402	6	713	th_val[6], threshold for 7 <sup>th</sup> layer in millivolts
402	7	713	th_val[7], threshold for 8 <sup>th</sup> layer in millivolts
402	8	713	th_val[8], threshold for 9 <sup>th</sup> layer in millivolts
402	9	713	th_val[9], threshold for 10 <sup>th</sup> layer in millivolts
402	10	713	th_val[10], threshold for 11 <sup>th</sup> layer in millivolts
402	11	713	th_val[11], threshold for 12 <sup>th</sup> layer in millivolts
402	12	9999	th_val[12], threshold for 13 <sup>th</sup> layer in millivolts
405	0	100	Integration threshold value for layer 1 (mV)
405	1	100	Integration threshold value for layer 2 (mV)
405	2	100	Integration threshold value for layer 3 (mV)
405	3	100	Integration threshold value for layer 4 (mV)
405	4	100	Integration threshold value for layer 5 (mV)
405	5	100	Integration threshold value for layer 6 (mV)
405	6	100	Integration threshold value for layer 7 (mV)
405	7	100	Integration threshold value for layer 8 (mV)
405	8	100	Integration threshold value for layer 9 (mV)
405	9	100	Integration threshold value for layer 10 (mV)
405	10	100	Integration threshold value for layer 11 (mV)
405	11	100	Integration threshold value for layer 12 (mV)
405	12	9999	Integration threshold value for layer 13 (mV)
602	-1	1017536	Echo sounder serial number
604	-1	306733	Transducer serial number
605	-1	Spd-4	Echogram paper speed
606	-1	9_pin	Echogram resolution
607	-1	Board_External	Trigger option
608	-1	LeftToRight	River flow direction

103	-1	32767	maxbott - maximum bottom range in samples NUS
104	-1	11	N_th_layer - number of threshold layers
105	-1	5	max_tbp - maximum time between pings in pings
106	-1	5	min_pings - minimum number of pings per fish
507	-1	FED5	timval - 0xFED5 corresponds to about 20 kHz NUS
108	-1	1	mux_on - means multiplexing enabled on board NUS
109	-1	200	mux_delay - samples delay between sync and switching NUS
110	-1	0	decimate_mask - decimate input samples flag NUS
112	-1	1	echogram_on - flag for DEP echogram enable 0=off, 1=on
113	-1	1	Hourly Sampling flag 1=On 0=Off
118	-1	5	maxmiss - maximum number of missed pings in auto bottom
119	-1	0	bottom-0=fix,1=man,2=scope,3=acq_chan1,4=acq_chan2,5=auto_1,6=auto_chan2
120	-1	0	sb_int_code - sb only=0, sb-int: 40log a bot=1, 20log=2
121	-1	0	sb_int_code2 - sb only=0, sb-int 40log eg=0, 20log=2
122	-1	11	N_int_layers-number of integration strata
123	-1	11	N_int_th_layers - number of integration threshold strata
124	-1	0	int_print - print integrator interval results to printer
125	-1	0	circular element transducer flag for bpf calculation
126	-1	80	grid spacing for Model 404 DCR (in samples, 16 s/m)
127	-1	1	TRIG argument #1 - trigger source
128	-1	0	TRIG argument #2 - digital data routing
130	-1	0	TVG Blank (0=Both Start/End,1=Stop Only,2=Start Only,3=None)
200	-1	20	sigma flag 0.0 = no sigma, else sigma is output
201	-1	218.07	sl - transducer source level
202	-1	-171.98	gn - transducer through system gain at one meter
203	-1	-18	rg - receiver gain used to collect data
204	-1	2.8	narr_ax_bw - vertical nominal beam width
205	-1	10	wide_ax_bw - horizontal axis nominal beam width
206	-1	0	narr_ax_corr - vertical axis phase correction
207	-1	0	wide_ax_corr - horizontal axis phase correction
208	-1	16	ping_rate - pulses per second
209	-1	0	echogram start range in meters
210	-1	32	echogram stop range in meters
211	-1	451	echogram threshold in millivolts
212	-1	13.2	print width in inches
213	-1	0	Chirp Bandwidth (0.0 = CHIRP OFF)
214	-1	40	Sampling within Hour Ending Time (in Decimal Minutes)
215	-1	1500	Speed of Sound (m/s)
216	-1	200	The Transducer's Frequency (kHz)
217	-1	-2.5	min_angoff_v - minimum angle off axis vertical
218	-1	2	max_angoff_v - maximum angle off axis vertical
219	-1	-5	min_angoff_h - minimum angle off axis horiz.

-continued-

## Appendix B2.-Page 2 of 3.

---

220	-1	5	max_angoff_h - maximum angle off axis horiz.
221	-1	-24	max_dB_off - maximum angle off in dB
222	-1	-15.7307	ux - horizontal electrical to mechanical angle ratio
223	-1	-54.9961	uy - vertical electrical to mechanical angle ratio
224	-1	0	ud_coef_a - a coeff. for up-down beam pattern eq.
225	-1	0.0434	ud_coef_b - b coeff. for up-down beam pattern eq.
226	-1	-2.3036	ud_coef_c - c coeff. for up-down beam pattern eq.
227	-1	-0.238	ud_coef_d - d coeff. for up-down beam pattern eq.
228	-1	-0.2092	ud_coef_e - e coeff. for up-down beam pattern eq.
229	-1	0	lr_coef_a - a coeff. for left-rt beam pattern eq.
230	-1	-0.0003	lr_coef_b - b coeff. for left-rt beam pattern eq.
231	-1	-0.2138	lr_coef_c - c coeff. for left-rt beam pattern eq.
232	-1	0.0004	lr_coef_d - d coeff. for left-rt beam pattern eq.
233	-1	-0.0001	lr_coef_e - e coeff. for left-rt beam pattern eq.
234	-1	4	maximum fish velocity in meters per second
235	-1	1	Echo Scope Bottom Location
236	-1	0.4	maxpw - pulse width search window size
238	-1	29.6	bottom - bottom depth in meters
239	-1	0	init_slope - initial slope for tracking in m/ping
240	-1	1	exp_cont - exponent for expanding tracking window
241	-1	0	max_ch_rng - maximum change in range in m/ping
242	-1	0.04	pw_criteria->min_pw_6 - min -6 dB pulse width
243	-1	10	pw_criteria->max_pw_6 - max -6 dB pulse width
244	-1	0.04	pw_criteria->min_pw_12 - min -12 dB pulse width
245	-1	10	pw_criteria->max_pw_12 - max -12 dB pulse width
246	-1	0.04	pw_criteria->min_pw_18 - min -18 dB pulse width
247	-1	10	pw_criteria->max_pw_18 - max -18 dB pulse width
249	-1	10	maximum voltage to allow in .RAW file
250	-1	0.2	TX argument #1 - pulse width in milliseconds
251	-1	25	TX argument #2 - transmit power in dB-watts
252	-1	-12	RX argument #1 - receiver gain
253	-1	62.5	REP argument #1 - ping rate in ms per ping
254	-1	10	REP argument #2 - pulsed cal tone separation
255	-1	2	TVG argument #1 - TVG start range in meters
256	-1	100	TVG argument #2 - TVG end range in meters
257	-1	40	TVG argument #3 - TVG function (XX Log Range)
258	-1	-6	TVG argument #4 - TVG gain
259	-1	0	TVG argument #5 - alpha (spreading loss) in dB/Km
260	-1	0.2	minimum absolute distance fish must travel in x plane
261	-1	0.2	minimum absolute distance fish must travel in y plane
262	-1	0.2	minimum absolute distance fish must travel in z plane
263	-1	2	bottom_window - auto tracking bottom window (m)
264	-1	3	bottom_threshold - auto tracking bottom threshold (V)
265	-1	11.2	TVG argument #7 - 20/40 log crossover (meters)
266	-1	0	rotator - which rotator to aim
267	-1	0	aim_pan - transducer aiming angle in pan (x, lf/rt)
268	-1	0	aim_tilt - transducer aiming angle in tilt (y, u/d)

---

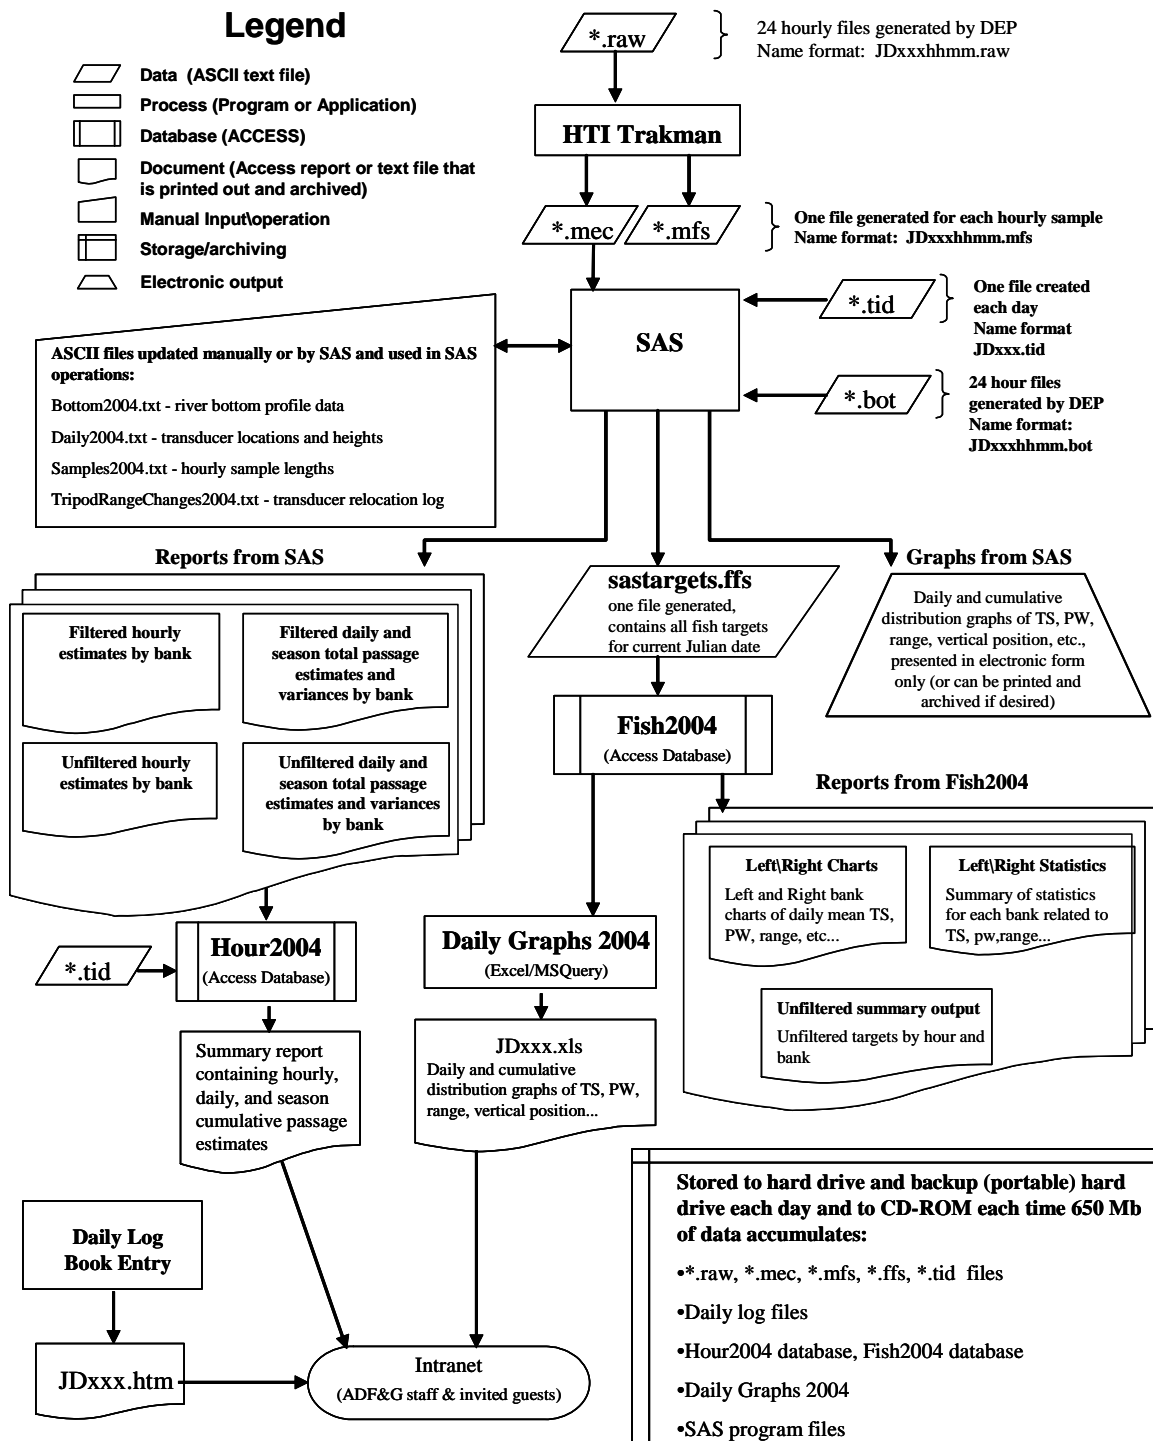

-continued-

## Appendix B2.-Page 3 of 3.

401	0	1	th_layer[0], bottom of 1 <sup>st</sup> threshold layer

Note: Bold and outlined numbers represent the dates that the Chinook fishery was restricted due to low inriver return.

<sup>a</sup> Sonar operations did not begin until 4 June, so the early run total passage estimate for 1987 is incomplete.

<sup>b</sup> Sonar operations began early (7 May) to determine the proportion of early run fish that may pass the site prior to the normal start date (16 May).

<sup>c</sup> Only upstream moving fish reported.

Note: Bold and outlined numbers represent dates when the Chinook fishery was restricted due to low inriver return.

<sup>a</sup> Late-run daily and total passage estimates for the years 1993 and 1994 were incorrectly reported in historical tables presented in previous reports (Bosch and Burwen 2000, Miller et al. 2002, Miller and Burwen 2002, and Miller et al. 2003). Estimates presented in this current table are correct and were originally reported by Burwen and Bosch 1995a; 1995b).

<sup>b</sup> Only upstream moving fish reported.

<sup>c</sup> Sampling was terminated on 5 August due to budget constraints. Values for 6-10 August were inferred from previous years.

<sup>d</sup> Sampling was terminated on 7 August following several consecutive days of passage less than 1% of the cumulative passage.

<sup>e</sup> Sampling was terminated on 7 August due to pink salmon spawning in the insonified area.

<sup>f</sup> Sampling was terminated on 9 August following several consecutive days of passage less than 1% of the cumulative passage.

<sup>g</sup> Sampling was terminated on 31 July due to pink salmon spawning in the insonified area.

<sup>h</sup> Sampling was terminated on 3 August following several consecutive days of passage less than 1% of the cumulative passage.

<sup>i</sup> Sampling was terminated on 3 August following three consecutive days of passage less than 1% of the cumulative passage.

**APPENDIX I. ECHO LENGTH STANDARD DEVIATION  
MIXTURE MODEL ESTIMATES OF SPECIES COMPOSITION  
AND CHINOOK ABUNDANCE, EARLY RUN 2004.**

We currently use a target strength threshold to help separate Chinook from sockeye salmon in the Kenai River. Target strength is a measure of the intensity (“loudness”) of an echo returning from a fish. Several years ago, we discovered that measurements of the length (duration) of echoes can be superior to target strength as predictors of fish size and species in side-looking riverine sonar applications (Burwen and Fleischman 1998, Burwen et al. 2003). Unfortunately, because the relationship between echo length and fish size is not perfect, and because Kenai River sockeye and Chinook salmon overlap in size, even echo length measurements cannot ascertain the species of individual fish.

In this situation a threshold-based approach (assigning individuals to one species or another depending on whether or not a measurement exceeds a threshold) has several important drawbacks. When distributions overlap, threshold-based discrimination is subject to bias that worsens for species proportions near 0 and 1 (Figure I1). Furthermore, results are sensitive to fish size distributions. For instance, in the example illustrated in Figure I1, the number of Chinook salmon misclassified as sockeye (number with ELSD < 2.7) depends largely on the relative abundance of small Chinook, which can change over time. In fact, use of such a threshold by itself does not discriminate Chinook from sockeye, but rather large Chinook from sockeye and small Chinook.

Consequently we have developed other methods, based on mixture models, which extract information about species composition from the frequency distribution of echo length measurements. Because the mixture model approach incorporates information about fish size distributions, and because it explicitly models the expected variability in hydroacoustic measurements, it is not subject to the above pitfalls. There is no bias against extreme proportions, and the estimates are germane to the entire population of Chinook salmon, not just those Chinook larger than sockeye. Finally, as long as length and hydroacoustic measurements are paired in time, mixture model estimates of species proportions are unbiased in the presence of temporal changes in fish size distribution.

Echo length standard deviation (ELSD) is used as the hydroacoustic correlate of fish size in the mixture models. Estimates based on the mixture model approach currently have two limitations. First, measurements of ELSD may be inflated when fish migrate at high densities, so thus far we have produced mixture model estimates only for the early run, when fish density remains low. Second, the mixture model requires empirical estimates of sockeye and Chinook length distributions from the gillnet catches. Limited gillnet sample sizes make it necessary to pool the data to produce weekly, rather than daily, estimates of species composition.

An abbreviated description of the mixture model approach is presented here, along with results from the 2004 early run. See Fleischman and Burwen (2003) for more details.

## **METHODS**

ELSD is calculated as,

$$ELSD = \sqrt{\sum_{j=1}^m (w_j - \bar{w})^2 / m - 1}, \quad (I1)$$

where  $m$  was the number of echoes and  $w_j$  was the length of the  $j^{th}$  echo measured in 48 kHz sample units at  $-12$  dB or higher, depending on peak echo amplitude. If peak amplitude was  $> 12$  dB above the voltage threshold, then echo length was measured at 12 dB below peak amplitude. If peak amplitude was 6-12 dB above the threshold, echo length was measured at the threshold. If peak amplitude was  $< 6$  dB above threshold,  $w_j$  was not defined.

Recent work (unpublished) indicates that targets located far from the acoustic axis may suffer a slight negative bias in ELSD. Therefore only those fish less than 3 dB off-axis were used in analyses reported here. These fish comprised 61% of all fish in the 2004 early run dataset.

The probability density function (pdf) of hydroacoustic variable  $y$  (= ELSD) was modeled as a weighted mixture of two component distributions arising from sockeye and Chinook salmon (Figure I2),

$$f(y) = \pi_S f_S(y) + \pi_C f_C(y), \quad (I2)$$

where  $f_S(y)$  and  $f_C(y)$  are the pdf's of the sockeye and Chinook component distributions, and the weights  $\pi_S$  and  $\pi_C$  are the proportions of sockeye and Chinook salmon in the population.

Individual observations of  $y$  were modeled as normal random variates whose mean was a linear function of fish length  $x$ :

$$y_i = \beta_0 + \beta_1 x_i + \gamma z_i + \varepsilon_i, \quad (I3)$$

where  $\beta_0$  was the intercept;  $\beta_1$  the slope;  $\gamma$  was the mean difference in  $y$  between sockeye and Chinook after controlling for length;  $z_i$  equaled 1 if fish  $i$  was a sockeye salmon, or 0 if Chinook; and  $\varepsilon_i$  was normally distributed with mean 0 and variance  $\sigma^2$ .

Thus the component distributions  $f_S(y)$  and  $f_C(y)$  were functions of the length distributions  $f_S(x)$  and  $f_C(x)$  and the linear model parameters  $\beta_0$ ,  $\beta_1$ ,  $\gamma$ , and  $\sigma^2$  (Figure I2). The species proportions  $\pi_S$  and  $\pi_C$  were the parameters of interest.

Length measurements were obtained from fish captured by gillnets (Reimer *In prep*) immediately downstream of the sonar site. Length data were paired with hydroacoustic data from the same time periods. In this analysis, we assume no gillnet size selectivity.

Sockeye and Chinook salmon return from the sea to spawn at several discrete ages. We modeled the species-specific length distributions as three-component normal age mixtures.

$$f_S(x) = \theta_{S1} f_{S1}(x) + \theta_{S2} f_{S2}(x) + \theta_{S3} f_{S3}(x), \quad (I4)$$

$$f_C(x) = \theta_{C1} f_{C1}(x) + \theta_{C2} f_{C2}(x) + \theta_{C3} f_{C3}(x), \quad (I5)$$

where  $\theta_{Ca}$  and  $\theta_{Sa}$  were the proportions of Chinook and sockeye salmon in age component  $a$ ,

$$f_{Sa}(x) \sim N(\mu_{Sa}, \tau_{Sa}^2), \text{ and} \quad (I6)$$

$$f_{Ca}(x) \sim N(\mu_{Ca}, \tau_{Ca}^2). \quad (I7)$$

The overall design was therefore a mixture of (transformed) mixtures. That is, the observed hydroacoustic data were modeled as a two-component mixture of  $y$ , each component of which was transformed from a three-component normal mixture of  $x$ .

We employed Bayesian statistical methods because they provide realistic estimates of uncertainty and the ability to incorporate auxiliary information. We implemented the Bayesian

mixture model in WinBUGS (Bayes Using Gibbs Sampler; Gilks et al. 1994). Bayesian methods require that prior probability distributions be formulated for all unknowns in the model. Species proportions  $\pi_S$  and  $\pi_C$  were assigned an uninformative  $\text{dirichlet}(1,1)$  prior. Likewise, age proportions  $\{\theta_{Sa}\}$  and  $\{\theta_{Ca}\}$  were assigned  $\text{dirichlet}(1,1,1)$  priors. Informative normal priors, based on historical data, were used for the length-at-age means  $\mu$  and standard deviations  $\tau$ . Informative priors were also used for regression parameters  $\beta_0$ ,  $\beta_1$ ,  $\gamma$ , and  $\sigma^2$ . Linear statistical models of tethered fish data reported by Burwen et al. (2003) provided estimates of the regression parameters with which to construct those prior distributions (Table I1).

WinBUGS uses Markov chain Monte Carlo methods to sample from the joint posterior distribution of all unknown quantities in the model. We started three Markov chains for each run and monitored Gelman-Rubin statistics to assess convergence. Some parameters exhibited slow mixing and large positive autocorrelations. Therefore relatively long burn-ins of 10,000 or more samples were used. Samples were thinned up to 10 to 1 thereafter, and at least 10,000 samples per chain were retained.

The end product of a Bayesian analysis is the joint posterior probability distribution of all unknowns in the model. For our model, this distribution has many dimensions and cannot be presented in its entirety. Generally, what is of interest are the marginal (one-dimensional) probability distributions of the parameters. These probability distributions can be graphed, and one can extract whichever statistics are needed, such as the mean, standard deviation, and/or various percentiles like 2.5, 5, 25, 50 (the median), 75, 95, 97.5. For values that can be interpreted as point estimates, we've chosen the posterior median. The interpretation of this value is as follows: there is an even (50/50) chance that the true value of the parameter lies above or below the posterior median. The posterior standard deviation (SD) is analogous to the standard error of an estimate from a classical (non-Bayesian) statistical analysis.

Sample size limitations necessitated pooling the data by week. Week one was 16-22 May, week six was 20-26 June, and week seven (incomplete, since the early run ended 30 June) was 27-30 June. Posterior medians of the Chinook proportion parameter  $\pi_C$  were multiplied by unfiltered sonar estimates  $\hat{x}_i$  to obtain estimates of absolute Chinook abundance  $y''$  for week  $w$ .

$$\hat{y}_w'' = \hat{\pi}_{Cw} \sum_{i \in w} \hat{x}_i . \quad (I8)$$

## RESULTS

Weekly statistics from the marginal posterior distributions of model parameters are summarized in Table I1. Posterior distributions of regression parameters shifted only slightly among weeks. Mixture model estimates totaled 17,264 (SE = 707) for the early run, slightly higher than the official estimate of 15,498 (SE = 261) and slightly lower than the net apportioned estimate of 17,998 (SE = 710). Modeled ELSD frequency distributions fit the weekly ELSD data reasonably well (Figure I3). Weekly mixture model estimates were between official estimates and net-apportioned estimates in most weeks (Figure I4). Weekly estimates by the two alternative methods have shown good agreement during 2002-2004 (Figure I5). Further comparisons of alternative early-run abundance estimates can be found in the main body of this report.

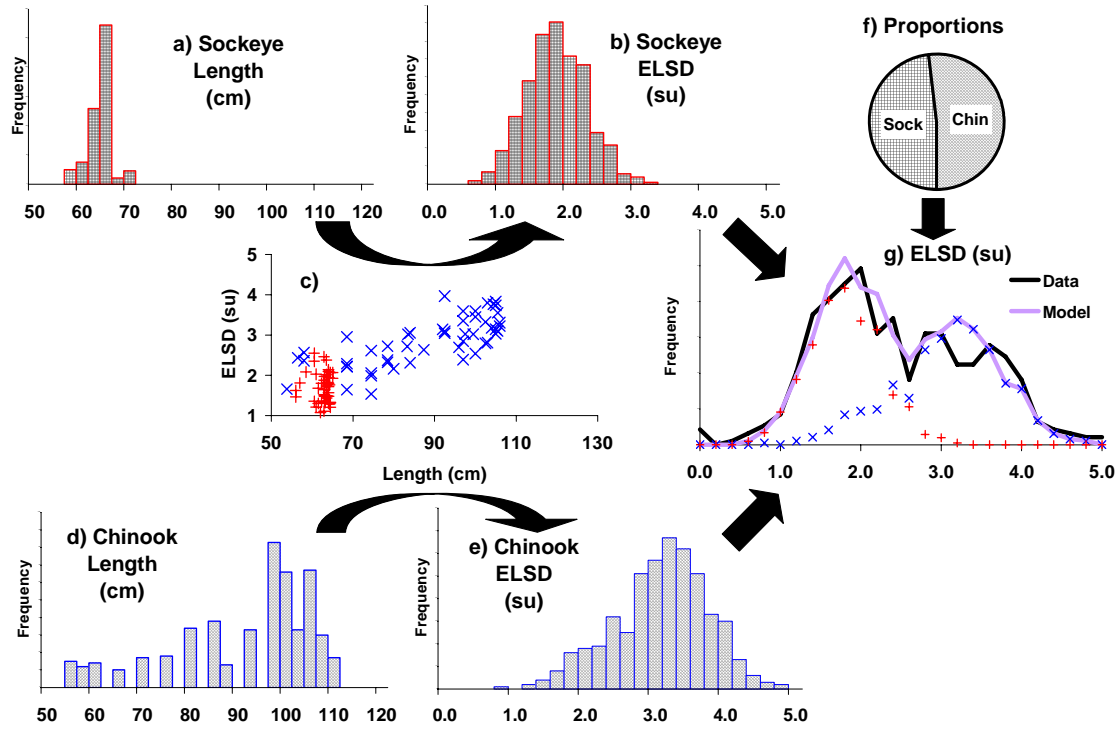

**Table 11.**-Summary statistics of prior and posterior distributions of parameters estimated from a Bayesian mixture model analysis of 7 weeks of Kenai River sonar and netting data, 2004.

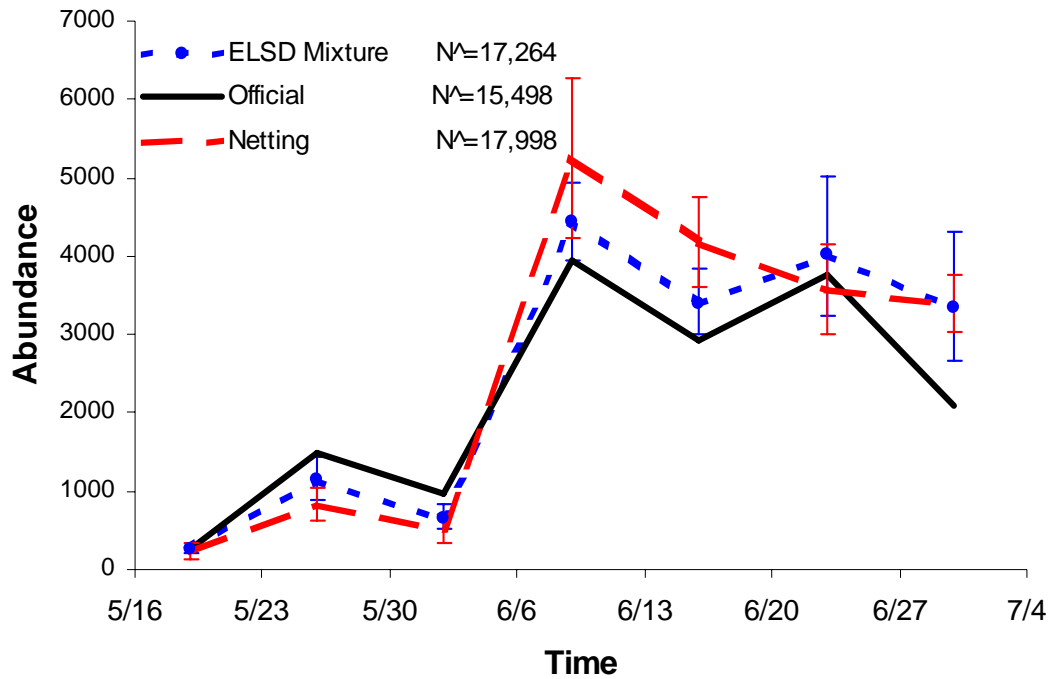

**Figure II.** Threshold-based discrimination is subject to bias when discriminating variables are imprecise. Solid lines are simulated frequency distributions of echo length standard deviation arising from component distributions due to sockeye salmon (plus symbols) and Chinook salmon (solid symbols). (a) If the true species composition is 50% sockeye/50% Chinook, and a threshold criterion of 2.7 is used, estimated species composition will be 60%/40%. (b) If the true species composition is 20%/80%, estimated species composition will be 38%/62%.

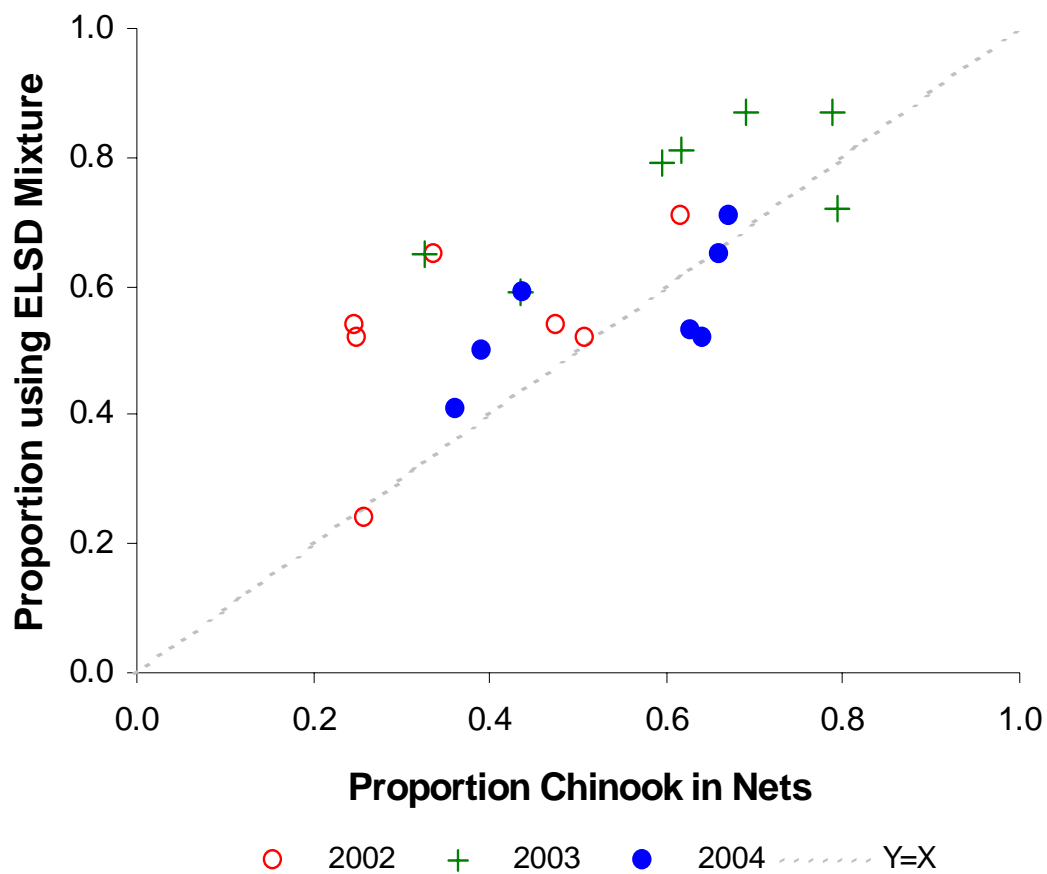

**Figure 12.-**Flow chart of mixture model described in the text. The frequency distribution of echo length standard deviation (ELSD, panel g) is modeled as a weighted mixture of species-specific ELSD distributions (b and e), which in turn are the products of species-specific size distributions (a and d) and the relationship between ELSD and fish length (c). The weights (species proportions, panel f) are the parameters of interest. Plus symbol = sockeye, x = Chinook. Checkered pattern = sockeye, cross-hatched = Chinook. Units for ELSD are 48 kHz digital sampling units.

**Figure I3.**—Observed (black) and fitted (gray) frequency distributions of echo length standard deviation (ELSD) from the 2004 early run, by week. Dotted lines are the component distributions from sockeye (left) and Chinook salmon (right). The posterior median of the proportion of Chinook salmon  $\pi_C$  is listed in the header of each panel.

**Figure I4.-**Weekly Chinook salmon abundance estimates for the 2004 Kenai River early run. Solid line = official estimates; dashed line = netting-apportioned estimates; dotted line = ELSD mixture model estimates. Error bars represent 95% intervals for netting and mixture estimates.

**Figure I5.-**ELSD mixture model estimates vs. net-apportioned weekly estimates of the proportion of Chinook salmon among fish passing the Kenai River sonar, early run 2002 (open symbols), 2003 (plus signs), and 2004 (solid symbols).
