August 2018

ADF&G Fishery Data Series was established in 1987 for the publication of Division of Sport Fish technically oriented results for a single project or group of closely related projects, and in 2004 became a joint divisional series with the Division of Commercial Fisheries. Fishery Data Series reports are intended for fishery and other technical professionals and are available through the Alaska State Library and on the Internet: <a href="http://www.adfg.alaska.gov/sf/publications/">http://www.adfg.alaska.gov/sf/publications/</a>. This publication has undergone editorial and peer review.

#### **ABSTRACT**

In 2017, the southern offshore test fishery (OTF) conducted from July 1 through July 31 captured 2,586 sockeye salmon *Oncorhynchus nerka*, which represented 2,194 catch per unit of effort (CPUE) index points. The midpoint of the 2017 sockeye salmon run at the southern OTF occurred on July 20. A formal inseason estimate of the 2017 run size was made on July 24 and this analysis predicted a total run to Upper Cook Inlet (UCI) of 7.11 million sockeye salmon. Therefore, the first best-fit total run estimate from the formal inseason projection of the 2017 run was approximately 54.2% higher than the actual run size. An inseason estimate was also made for the Kenai River sockeye salmon run on July 24; the July 24 analysis predicted a total run to the Kenai River that range of 1.6–4.3 million fish. Sockeye salmon and coho salmon *O. kisutch* genetic samples were collected from the OTF and archived for future analysis.

Key words: Pacific salmon, *Oncorhynchus* spp., test fishery, migratory behavior, mixed stock analysis, MSA, Upper Cook Inlet, Alaska

#### INTRODUCTION

In 1979, the Alaska Department of Fish and Game (ADF&G) began an offshore test fishery (OTF) project (hereafter referred as the southern OTF) near the southern boundary of the Upper Cook Inlet (UCI) salmon management area between Anchor Point and the Red River Delta (Figure 1). The project was designed to estimate the total sockeye salmon *Oncorhynchus nerka* run (including run timing) returning to UCI during the commercial salmon fishing season. These data are used to help adjust commercial fishing times and areas to most efficiently harvest surplus sockeye salmon or restrict fisheries that may overharvest specific stocks. In recent years, the Alaska Board of Fisheries (BOF) has assembled management plans requiring inseason abundance estimates of the annual sockeye salmon run to implement specific plan provisions. The southern OTF project has increasingly become one of the most important tools Upper Cook Inlet fishery managers utilize to make inseason fishery management decisions that comply with BOF management directives. Test fishery results have been reported annually since 1979 (e.g., Dupuis et al. 2016).

In 2012, a second test fishery project (hereafter referred as the northern OTF) was added. This project collected tissue samples from sockeye salmon for genetic stock identification in order to assess the spatial and temporal separation of Susitna River sockeye salmon as they migrate through Cook Inlet. From 2012 to 2013, the northern OTF vessel fished 7 stations along a single transect; in 2014, the vessel fished 8 stations along 2 transects running from Kalifornsky Beach to the northern tip of Kalgin Island (Stations 2–5) and from the southern tip of Kalgin Island to Clam Gulch Beach (Stations 8–11; Figure 2). The modification to the northern OTF was made because it was believed that, due to the lack of fish encountered at the omitted stations (Dupuis et al. 2015), ADF&G could more efficiently gather spatial and temporal information by adding the second transect. The northern OTF project was discontinued prior to the 2015 season due to a lack of funding. This report presents the results of the 2017 southern offshore test fishery project and historic genetic stock identification information collected from both the northern and southern test fisheries.

#### **OBJECTIVES**

The objectives of the southern OTF project were as follows:

- 1. Develop an inseason estimate of the 2016 UCI sockeye salmon total run;
- 2. Develop an inseason estimate for the 2016 Kenai River sockeye salmon total run; and

3. Estimate the spatial and temporal distribution of various sockeye salmon and coho salmon *O. kisutch* stocks entering UCI.

#### **METHODS**

#### **TEST FISHERY**

The southern OTF sampled salmon returning to UCI by fishing 6 geographically fixed stations, which were numbered consecutively from east to west (Figure 1). The current southern OTF stations have been fished since 1992 (Tarbox 1994) and provide the most reliable estimates of inseason run size and timing. Station 6.5 was not fished prior to 1992; analyses concluded that the addition of Station 6.5 increased sampling power, but did not alter estimates of run timing (Tarbox and King 1992). The ADF&G vessel R/V *Solstice* sampled all 6 stations of the southern OTF transect daily, traveling east to west on odd-numbered days and west to east on even-numbered days. Sampling began on July 1 and the project concluded on July 31. Catch and catch per unit effort (CPUE) data for missed stations were generally interpolated using a simple average of catches from the day before and the day after for each station not fished. However, on July 13, daily total CPUE was estimated using a regression relating commercial drift gillnet to OTF CPUE ( $R^2 = 0.522$ , df = 8, P = 0.028), because the commercial drift gillnet fleet was fishing near the OTF transect on that day.

The following physical and chemical measurements were taken at the start of each gillnet set at each station: air temperature, water temperature and salinity (at 1 m below the surface), wind velocity and direction, tide stage, water depth, and water clarity. Air and water temperatures (°C) and salinity (ppt) were measured using an YSI Model Pro30 conductivity/salinity/temperature meter (YSI Inc.; Yellow Springs, OH)<sup>1</sup>. Wind speed was measured in knots and direction was recorded as 0 (no wind), 1 (north), 2 (northeast), 3 (east), 4 (southeast), 5 (south), 6 (southwest), 7 (west), or 8 (northwest) using a pocket weather tracker. Tide stage was classified as 1 (high slack), 2 (low slack), 3 (flooding), or 4 (ebbing) by observing the movement of the vessel while drifting with the gill net. Water depth was measured in fathoms (fm) using an echo sounder and water clarity was measured in meters (m) using a 17.5 cm Secchi disk, following methods described by Koenings et al. (1987).

A conductivity-temperature-depth profiler (CTD) was also deployed at each station beginning July 14 along the southern OTF transect. The CTD measured temperature (°C), salinity (psu; psu is defined as practical salinity unit and is equivalent to ppt), chlorophyll a (mg/m³), oxygen (percent saturation) and photosynthetically active radiation (PAR, percent surface maximum) throughout the water column. The CTD was lowered to within about 3 m of the bottom and retrieved at 1 m/sec. Salinity values reported from July 1 to 13 were adjusted postseason due to low salinity values reported using the YSI Model Pro30 Instrument. A simple linear regression using the recorded salinity values from the YSI Model Pro Instrument and the recorded salinity values from the CTD during the July 14 to 31 sample was used to adjust salinity values recorded from July 1 to 13. In this report, a cross-section of monthly mean parameter distributions along the southern OTF transect is presented.

The southern OTF vessel fished 366 m (1,200 ft or 200 fathoms) of multi-filament drift gillnet using a mesh size of 13 cm (5 1/8 inches). The net was 45 meshes deep and constructed of

2

Product names used in this report are included for scientific completeness, but do not constitute a product endorsement.

double knot Super Crystal shade number 1, with filament size 53/S6F. At each station, all salmon captured in the drift gillnet were identified by species and enumerated. Sockeye salmon captured at the southern OTF ( $n \le 30$  at each station) were measured for length (mid eye to tail fork) to the nearest mm.

For each species of salmon, the number of fish captured at each station (s) on each fishing day (i) was expressed as a CPUE statistic, or index point, and standardized to the number of fish caught in 100 fathoms of gear in 1 hour of fishing time:

$$CPUE_{s,i} = \frac{100 \, fm \times 60 \, \text{min} \times number \, of \, fish}{fm \, of \, gear \times MFT} \,. \tag{1}$$

Mean fishing time (*MFT*) was:

$$MFT = (C - B) + \frac{(B - A) + (D - C)}{2}$$
, (2)

A is the time that net deployment started, B is the time that the net fully deployed, C is the time net retrieval started, and D is the time the net was fully retrieved.

Once deployed at a station, the drift gillnets fished 30 minutes before retrieval. However, the net was capable of capturing fish prior to being fully deployed and during the time it was being retrieved. *MFT* was therefore adjusted by summing the total time it took to set and retrieve the net, then dividing this time in half, and adding it to the time when the entire net was deployed and fished (Equation 2).

Daily  $CPUE_i$  data were summed for all m stations (typically 6) as follows:

$$CPUE_i = \sum_{s=1}^{m} CPUE_{s,i} . (3)$$

Cumulative  $CPUE_i$  ( $CCPUE_d$ ) was given by:

$$CCPUE_d = \sum_{i=1}^{d} CPUE_i , \qquad (4)$$

where d is the date of the estimate.

#### GENETIC STOCK IDENTIFICATION SAMPLING

#### **Tissue Sampling**

Sockeye salmon captured at each station on the southern OTF ( $n \le 50$ ) had the left axillary process removed for genetic analysis (Habicht et al. 2007). Additionally, in 2017, all coho salmon captured had the left axillary process removed for future genetic analysis. Once removed, the axillary process from individual fish was then placed on a sample card for later analysis. For data continuity, sockeye salmon tissue samples from the southern OTF were paired with corresponding length information. These data were collated and archived at the Gene Conservation Laboratory in Anchorage.

#### DESCRIBING THE SALMON MIGRATION AND PROJECTING TOTAL RUN

For the southern OTF, the sockeye salmon run was described for each of the previous years based on the respective test fishery data, as described in Mundy (1979):

$$Y_{\text{vr.}d} = 1/(1 + e^{-(a+bd)})$$
, (5)

where  $Y_{yr,d}$  is the modeled cumulative proportion of  $CCPUE_{yr,f}$  (f is the final day of season) for year (yr) as of day (d), and a and b are model parameters.

Variables without the subscript yr refer to the current year's estimate. To determine which of the previous run timing curves most closely fit the current year's data on day (d), and to estimate total run for the entire season  $(TR_f)$ , a projection of the current year's  $CCPUE_d$  at the end of the season (CCPUEF) was estimated as per Mundy (1979):

$$CCPUEF = \frac{\sum_{d=0}^{D} CCPUE_d^2}{\sum_{d=0}^{D} Y_{yr,d} \cdot CCPUE_d}.$$
(6)

This model assumes that the modeled cumulative proportions  $(Y_{yr,d})$  for previous year (yr) are the same as for the current year (Mundy 1979). To test this assumption, inseason  $Y_d$  was estimated as:

$$Y_d = \frac{CCPUE_d}{CCPUEF} , (7)$$

and mean squared error (MSE) between  $Y_d$  and  $Y_{yr,d}$  was estimated as:

$$MSE = \frac{\sum_{d=0}^{D} (Y_{yr,d} - Y_d)^2}{D+1}.$$
 (8)

Years were ranked from lowest *MSE* (best model) to highest (worst), and the best-fit years were used to estimate *CCPUEF* for the current year. Catchability, or the fraction of the available population taken by a defined unit of fishing effort, was estimated as:

$$q_d = \frac{CCPUE_d}{r_d}, \tag{9}$$

where  $q_d$  is the estimated cumulative catchability as of day (d), and  $r_d$  is the cumulative total run as of day (d).

The cumulative total run on day (d) was the sum of all estimates for commercial, recreational, and personal use harvests to date, total escapement to date, and the number of residual (i.e., residing) sockeye salmon in the district. The commercial harvest was estimated inseason from mandatory catch reports that were called or faxed into the ADF&G office. Personal use and recreational harvests were estimated inseason by examining catch statistics from previous years' fisheries of similar sized runs. Total passage to date included estimated passage into all

monitored systems (Susitna, Kenai, and Kasilof rivers, and Fish Creek) and unmonitored systems, which are assumed to be 15% of the passage into monitored systems (Tobias and Willette 2003). The number of residual fish in the district was estimated by assuming exploitation rates of 70% in setnet fisheries, 35–40% in districtwide driftnet fisheries (based on the number of boats that fished), and 25% in reduced district driftnet fisheries (Mundy et al. 1993). For example, if the drift gillnet fleet harvested 500,000 sockeye salmon during an inletwide fishing period, the number of sockeye salmon originally in the district would be 1,250,000 (500,000/0.40 = 1,250,000) and the number remaining, or the residual, is 750,000 (1,250,000–500,000 = 750,000).

The passage rate  $(PR_d)$ , as of day (d), is the expansion factor used to convert CPUE into estimated numbers of salmon passing the test fishery transect line into UCI:

$$PR_d = 1/q_d . (10)$$

Total run at the end of the season  $(TR_f)$  was:

$$TR_f = PR_d \cdot CCPUEF.$$
 (11)

The midpoint of the run (M), defined as the day that approximately 50% of the total run has passed the southern OTF transect from day 1 (June 24), was:

$$M = -a/b, (12)$$

where a and b are model parameters.

The last day of test fishing typically occurs on July 30 each year, which means the "tail-end" of the sockeye salmon run was not assessed by the project. In 2017, the southern OTF project ended on July 31, but escapement monitoring continued through August 20 in the Kasilof River, August 24 in the Kenai River, August 28 at Fish Creek, and into late August at Judd, Chelatna, and Larson lakes. Commercial fishing also continued into September.

Because the test fishery does not encompass the entire sockeye salmon run, the total *CCPUEF* for the test fishery is estimated postseason using 2 methods (Equations 13 and 14):

$$CCPUE_f^h = CCPUEF \cdot \frac{H_t}{H_I} , \qquad (13)$$

where  $CCPUE_f^h$  is the total estimated CCPUEF for the season, based on harvest,  $H_t$  is the total commercial harvest for the season,  $H_L$  is the total commercial harvest through final day of test fishery (f+2), and L is the number of days (lag time) it took salmon to travel from the test fishery to commercial harvest areas (2 days, Mundy et al. 1993):

$$CCPUE_{t}^{r} = CCPUEF \cdot \frac{E_{t} + H_{t}}{E_{L} + H_{L}}, \tag{14}$$

where  $CCPUE_t^r$  is total estimated CCPUEF for the season, based on total run,  $E_t$  is the total escapement for the season,  $H_t$  is the total commercial harvest for the season,  $E_L$  is the total UCI escapement through the final day of the test fishery, summed from 6 different streams,  $H_L$  is the total UCI commercial harvest through the final day of the test fishery, and L is the number of

days (lag time) it took salmon to travel from the test fishery to spawning streams or commercial harvest areas.

The total run adjustment to CCPUEF (Equation 14) has replaced adjustments based on harvest alone (Equation 13), primarily due to changes to commercial fishing management plans made by the Alaska Board of Fisheries. Management plans now provide less fishing time in August than in the past; therefore, adjustments based on harvest alone would not have accurately reflected the additional fish that entered the district after the test fishery ceased. The total run to date on the last day of the test fishery was the sum of all commercial harvest data and escapement. Escapement estimates were derived by summing passage from 2 sockeye salmon sonar enumeration sites (Kenai and Kasilof rivers) and adding to that an expansion of the cumulative weir counts at Chelatna, Judd, and Larson lakes to reflect the total Susitna River sockeye salmon escapement, plus the weir count at Fish Creek, and an estimate of escapement to all unmonitored systems through day (d). Total Susitna River sockeye escapement ( $E_S$ ) was estimated by expanding the sum of weir counts at Chelatna ( $E_C$ ) and Judd ( $E_J$ ) lakes by a factor of 2.3 and the Larson lake weir count ( $E_L$ ) by a factor of 1.9, e.g.

$$E_s = ((E_C + E_I) \cdot 2.3) + (E_I \cdot 1.9). \tag{15}$$

The expansion factor for Chelatna and Judd lakes was estimated from mark–recapture studies conducted in 2008–2015 (Yanusz et al. 2007, 2011a, 2011b; Willette et al. 2016) and the expansion factor for Larson Lake was estimated from mark-recapture studies conducted in 2006–2008 (Yanusz et al. 2007, 2011a, 2011b).

An estimate of escapement to all non-monitored systems in UCI was considered to be 15% of the monitored runs (Tobias and Willette 2003). Lag times are the approximate time for fish to migrate from the test fishery transect to a particular destination. As suggested by Mundy et al. (1993), lag times must be considered when estimating the total run passing the test fishery transect on day (*d*). A lag time of up to 2 days was assumed for fish harvested in the commercial fishery. We estimated lag times between the test fishery and escapement projects as follows: Kasilof and Kenai rivers, 4 days; Fish Creek, 7 days (Mundy et al. 1993); and Susitna River weirs, 14 days. The number of sockeye salmon harvested in sport and personal use fisheries after test fishing has ceased that have not been estimated in the escapement are assumed to be insignificant, and therefore are not utilized in the *CCPUEF* post-test-fishery adjustment.

Adjusted estimates of CCPUEF ( $CCPUE_t^h$  and  $CCPUE_t^r$ ) were used for postseason estimates of  $TR_f$ .

#### PROJECTING THE KENAI RIVER TOTAL RUN

In addition to making inseason estimates of the total size of the annual sockeye salmon run, UCI commercial fishery management plans require ADF&G to make an inseason estimate of the number of Kenai River sockeye salmon in the run. Various management actions in both sport and commercial fisheries are tied to the total abundance of Kenai River sockeye salmon, which is characterized by 3 different size ranges: less than 2.3 million fish, between 2.3 and 4.6 million fish, and greater than 4.6 million fish (Shields and Frothingham 2018). As previously described, the *CCPUED* curves from the top 5 best fits of previous year's test fishery data were used to project the *CCPUEF* in 2017, which was then used to estimate the UCI total run. The Kenai River component of the run was determined in part from a weighted age-composition allocation

method to estimate the stock composition of the commercial harvest (Tobias and Tarbox 1999). This method (Bernard 1983) allocates the commercial harvest to various stocks by comparing the age composition of the escapement in the major river systems of UCI to the age composition of sockeye salmon harvested commercially (Tobias and Willette 2004). Three important assumptions of the weighted age-composition method are that: 1) the age compositions of fish escaping into the various river systems are representative of the age composition in the commercial harvest; 2) the commercial harvest in specific areas is composed of nearby stocks; and 3) exploitation rates are equal among stocks within age classes. The Kenai River run to date  $(TRK_d)$  was estimated by summing: 1) the commercial harvest of Kenai River stocks; 2) the estimated (using dual-frequency identification sonar (DIDSON)) passage of sockeye salmon in the Kenai River; and 3) an estimate of sport and personal use harvest below the river mile 19 sonar site. Finally, the remainder of the run that will be Kenai River origin was projected by subtracting the run to date from the total run estimate, and then applying an estimate of the proportion of the run remaining that will be Kenai River  $(PK_d)$  by reviewing previous years' data for runs of similar timing. The total Kenai River run  $(TRK_f)$  was estimated from:

$$TRK_f = ((TR_f - r_d) \cdot PK_d) + TRK_d. \tag{16}$$

#### RESULTS AND DISCUSSION

#### **TEST FISHERY**

In 2017, the southern OTF boat fished 156 of the possible 186 gillnet sets (e.g., 6 possible sets per day for 31 days; Table 1). A total of 2,586 sockeye salmon were captured during the 2017 test fishery, as well as 510 pink *O. gorbuscha*, 1273 chum *O. keta*, 642 coho and 2 Chinook salmon *O. tshawytscha* (Tables 1–3; Appendices A1–A13). Sockeye salmon daily catches ranged from 25 fish on July 21 to 328 fish on July 11. The 2017 sockeye salmon *CCPUEF* was 2,194 and daily CPUE values ranged from 20 to 216 (Tables 1 and 3). Linear regression of historic data showed that the 1992–2017 annual test fishery unadjusted *CCPUEF* and the total annual run of sockeye salmon to UCI (Figure 3) were significantly ( $\alpha = 0.05$ ) correlated (P = 0.03 and P = 0.19), and 81% of the variation was unexplained. Because so much of the variation remains unexplained, the southern OTF *CCPUEF* by itself may not be a reliable predictor of the total annual sockeye salmon run.

#### INSEASON ABUNDANCE ESTIMATES

Tarbox and Waltemyer (1989) provided detail about the assumptions used in the curve fitting procedures to estimate the *CCPUEF* statistic during the season. One of the major assumptions was that 24 June represents the first day of the sockeye salmon run to UCI. Variability in estimated runs can therefore result in an average or early run being misclassified as late, especially during the first 2 weeks of the test fishery program. For this reason, 20 July was chosen as the earliest date that inseason formal estimates of each year's total run size and run timing should be made. By then, there are enough data points in the current year's run timing curve to provide a more accurate estimate of the *CCPUEF*. In addition, Tarbox and King (1992) and later *Migratory timing and abundance estimates of sockeye salmon into Upper Cook Inlet, Alaska* annual project reports demonstrated that the initial first choice (best fit) estimate of the *CCPUEF* statistic and total run made around mid-July was often not the best-fit estimate later in July. Therefore, when making formal inseason estimates of the total run, the top 5 or 6 best fits

are evaluated. Careful consideration was given to years whose fits reveal the least day to day change in the predicted *CCPUEF*. These years are identified as potentially being the final best fit at the end of the season, especially if the *MSE* (Equation 8), also referred to as the mean sum of squares, statistic was also improving. Salmon run timing information from other areas of Alaska are also considered to help predict UCI run timing (Willette et al. 2010).

The formal abundance estimate of the 2017 UCI sockeye salmon run occurred on July 24, using commercial, sport and personal use harvests, escapement, and test fishery data through July 20 (Table 4). The 2017 test fishery *CCPUED* curve was mathematically compared to run curves from 1979 through 2016 (no estimate was made for 2013), and the estimates were ranked from best to worst based on MSE. The passage rate was estimated to be 1,617 based on a run of 2.4 million fish through July 20 (includes residual fish abundance in the district). The 2017 test fishery *CCPUED* curve most closely tracked the 2006 run, estimating a *CCPUEF* of 4,394 index points. Given a passage rate of 1,617, the total run estimate was 7.11 million fish. As cautioned earlier, the first best fit (lowest MSE) on approximately 20 July often turned out not to be the best fit at the end of July. The top 5 fits considered used commercial, sport, and personal use harvest through July 24, which included run timing curves from 2000, 2009, 2005, and 1996 (in order of best fit). Using these data, total run estimates ranged from 3.0 million to 7.1 million sockeye salmon. The best fits included runs between 2 days early and 7 days late.

The total sockeye salmon run to UCI in 2017 was estimated at approximately 4.61 million fish, including commercial, sport, and personal use harvests, as well as escapement to all systems (Table 5). Therefore, the first best-fit total run estimates from the formal inseason projection of the 2017 run was approximately 54.2% higher than the actual run size. However, because the top 5 best fits from each analysis were given careful consideration inseason, the range in error from these projections are highlighted in this report. Based on data through July 24, the difference between the projected total run to UCI and the actual value ranged between 23.6% and 54.2%.

Using the July 24 total UCI run estimate, the total Kenai River sockeye salmon run was projected to range between 1.62 and 4.33 million fish (Table 6). Assuming 1.29 million Kenai River sockeye salmon had returned to date, that meant 330,000 to 3.05 million fish remained in the run. The preseason forecast for the Kenai River had projected a total run of 2.2 million fish, requiring commercial fisheries management to follow guidelines for a run less than 2.3 million sockeye salmon. Three of the 5 best-fit estimates from the July 24 assessment projected a Kenai River run below 2.3 million fish; the remaining estimates projected a run between 2.3 and 4.6 million fish. However, on July 29, an inseason assessment indicated to ADF&G that the run would exceed 2.3 million sockeye salmon. Using postseason data, the 2017 sockeye salmon run to the Kenai River was estimated to be approximately 2.89 million fish.

#### **OTF Error**

OTF run forecast errors are largely a function of errors in estimating *CCPUEF*, which result from the algorithm that fits the current year's cumulative *CPUE* to run timing curves from earlier years. Early in the season, the curve fitting algorithm tends to estimate that the current year's run timing curve best-fits curves from previous years with later run timings, resulting in overestimates of *CCPUEF*. Thus, forecast errors for total run, *CCPUEF*, and run timing tend to be positive early in the season, and decrease significantly as the season progresses (Figure 4). After approximately July 23, run forecast errors tend to stabilize within plus or minus 20%. Mean absolute percent errors (MAPE) average 40% from July 19–23, 9% from July 24–26 and

7% from July 27–31 (1996–2014). Prior to July 24, the model tends to over forecast small runs and more accurately forecast large runs, whereas forecast errors from July 24–26 are weakly positively related to run size, and forecast errors from July 27–31 are not related to run size (Figure 5). Prior to July 24, forecast MAPE was also a function of actual run timing (Table 5; Figure 6). MAPE was 34% for early runs and 17% for on-time or late runs. Forecast errors are also a function of actual run size.

In 2017, the first best-fit estimate for July 24 was not the most accurate and overestimated the final UCI total sockeye salmon run by 54.2%. The model selected the 2006 sockeye salmon run as the best fit. The 2006 run was late and above average in run size; by late July, there was confidence among ADF&G management staff that 2017 would be late by an unknown amount and would probably be slightly larger than forecasted. Only July 31, the best-fit estimate was the 1998 run, which was very close to the 2017 run with respect to run timing and total run size. This highlights the importance that management staff should consider all of the top 5 best-fit estimators as possible predictors of run timing and run strength.

#### **RUN TIMING**

Although differences between annual inseason and postseason (adjusted by either harvest or total run) *CCPUEF* statistics were often relatively minor, they affected calculations of the *a* and *b* coefficients in the equations used to describe historical run timing curves (Equation 5), which in turn had an effect on estimates of subsequent *CCPUEF* values (Table 7). Beginning in 2002, the total run method was used to make postseason adjustments to all previous years' *CCPUEF* statistics (Shields 2003).

For the 2017 season, the test fishery *CCPUEF* of 2,194 was adjusted to 2,912 based on the number of fish that were commercially harvested and escaped after the test fishery ceased (Table 7). Therefore, this method estimated that approximately 25% of the sockeye salmon run occurred after the test fishery terminated (Appendix A14). Historical *a* and *b* coefficients calculated using total run-adjusted *CCPUEF* values are now used for all inseason run projections.

A nonlinear mathematical model (Mundy 1979) was fit to the *CCPUED* proportions of the 2017 sockeye salmon run to UCI. Using the total run-adjusted *CCPUEF*, this analysis suggested that 1% of the run had passed the OTF transect line prior to the start of the test fishery on July 1, and that the run was approximately 75% complete at project termination on July 31 (Appendix A14). Therefore, the mathematical model suggested the 2017 test fishery covered approximately 74% of the run. The test fishery passage rate for the season can be calculated by dividing the total number available to capture by the test fishery by the unadjusted *CCPUEF*. In 2017, the estimated final passage rate was approximately 1,564.

The midpoint of the 2017 UCI sockeye salmon run, or the day on which approximately 50% of the total run had entered UCI at the test fishery transect, occurred on day 27.3, or July 20, which was 4 days late compared to the historical mean date of July 16 (Table 8).

#### ENVIRONMENTAL VARIABLES

In 2017, surface water temperatures measured along the southern OTF transect ranged from 8.4°C to 12.1°C and averaged 12.2°C for the year (Appendices A15–A16). These water temperature data were below the 1992–2016 average surface water temperature of 10.5°C (Appendix A17). Air temperatures ranged from 11.5°C to 19°C and averaged 16°C. Wind

velocity averaged 10 knots for the month. Wind direction was variable, but in general, winds originated out of the southeast, the predominate wind orientation in UCI during July. The 2017 seasonal average salinity of 30.6 ppt was higher than the 1992–2016 average of 29.7 ppt. Koenings et al. (1987) describe a Secchi disk as a black and white circular plate that is used to easily estimate the degree of visibility in natural waters. Secchi disk readings in 2017 was slightly lower than averages from all previous years. In general, water clarity along the test fishery transect decreases as you travel from east to west as a result of numerous glacial watersheds draining into the west side of Cook Inlet. From 2002 to 2017, the average Secchi disk depth was 7.8 m at Station 4 and decreased to 3 m at Station 8. Finally, Station 4 was the shallowest station, averaging 9 fathoms (55 feet) in depth. Changes in depth are a result of different stages of tide as well as minor differences in set location from day to day.

Monthly mean distributions of temperature and salinity along the southern OTF transect in 2017 indicated cooler surface temperatures and higher surface salinities compared to 2014–2016 (Figure 7). A core of relatively low-temperature, high-salinity water was evident below about 30 m depth along the west side of the transect sloping upward to the surface along the east side of the transect. Oxygen saturation and chlorophyll *a* levels were generally higher near this core of cooler water at depth. Surface layer water temperatures were about 1–2°C cooler and salinities were higher in 2017 than in 2016.

Water temperatures are believed by many to play a significant role in the timing of salmon runs (Burgner 1980), therefore these data have been closely monitored. In general, warmer water temperatures are thought to result in early runs, whereas cooler temperatures produce later runs. For example, in Bristol Bay, Burgner (1980) reported that the arrival dates of sockeye salmon were early during years when water temperatures were warmer than average. In a later Bristol Bay study, Ruggerone (1997) found that the change in temperature from winter to spring was a better predictor of run timing than water temperature alone. However, water temperature data alone may or may not be an accurate predictive tool for gauging the run timing of UCI salmon stocks. The 2005 UCI sockeye salmon run was the second latest run ever observed, yet surface water temperatures along the test fishery transect were the warmest ever measured. Conversely, the 2008 run was 4 days early, yet surface water temperatures were much cooler than average. Therefore, it appears that factors other than just water temperature probably play a role in determining salmon run timing in UCI. Pearcy (1992) summarized some of the factors that affect the coastal migration of returning adult salmon and found that prior to entering estuaries adult salmon probably rely on cues that are different from those used in the open ocean phases of their migration.

Although salinity, water temperature, currents, and bathymetry are all believed to play a role in migration, another dynamic to consider that could affect run timing to UCI is the stock composition of the run. When classifying total sockeye salmon run timing in UCI, the magnitude of the Kenai River run should be considered. Because Kenai River sockeye salmon return to UCI later and in larger numbers than any other stock, UCI runs classified as late tend to include large Kenai River runs. For example, from 1988 to 2015, the average Kenai River total run (DIDSON-based) for years when the UCI return was classified as early (n = 12), was 3.4 million fish, yet for UCI runs classified as on time or late (n = 17), the Kenai River run averaged 4.2 million fish. A combination of these factors (water temperature, salinity, currents, bathymetry, and stock composition of the run) probably affects fish migration and ultimately classifying the run timing as early or late.

To better understand and predict sockeye salmon migrations into UCI, ADF&G conducted a companion study on the test fishery vessel from 2002 to 2005. Using side-looking sonar, fish distribution in the water column was measured in relation to various oceanographic data, such as water temperature, salinity, tide stage, and water clarity. This study also examined various methods for improving the OTF inseason run forecasts (Willette et al. 2010).

#### GENETIC STOCK IDENTIFICATION TISSUE SAMPLING AND ANALYSES

For the 2017 southern OTF, tissues suitable for genetic analysis were sampled from 2,089 sockeye salmon and these samples were archived for future analysis. In 2017, 608 coho salmon were sampled from the southern OTF project. Data retrieval and quality control results for the baseline collections are reported in Barclay and Habicht (2012).

Genetic information has been collected and analyzed from the southern OTF since 2006 and from the northern OTF from 2012 to 2014 (Dupuis and Willette 2016). The efficacy of using MSA in combination with the test fishery for inseason management of the UCI commercial fishery remains unclear. Although it could be useful to know when specific stocks are entering the Central District, inter- and intra-annual variability in migration routes through the district would make adjusting commercial fishing periods to increase or decrease stock-specific exploitation problematic. Willette et al. (2016) provides a review of the temporal and spatial distributions of Kenai and Susitna sockeye salmon and coho salmon in UCI. The UCI test fishery continues to provide fishery managers with important data about sockeye salmon stock composition, abundance, and run timing. Because commercial, sport, and personal use fishery management plans depend on inseason sockeye salmon run estimates, the UCI test fishery project remains one of the most essential tools available for the implementation of these plans.

#### **ACKNOWLEDGEMENTS**

The authors would like to thank the captain and crew of the R/V *Solstice* for conducting safe and efficient maritime activities.

Table 5.—Absolute percent error (APE) using the first best-fit estimate of southern test fishery data on or after July 20 to project the estimated total annual UCI sockeye salmon run 1988–2017.

	Actual run	July 20		
Year	(millions)	estimate	APE	Run timing
1988	8.52	11.30	32.6%	1 day early
1990	5.00	4.90	1.9%	4 day late
1991	3.66	3.90	6.5%	2 day late
1992	10.90	11.40	4.5%	2 day late
1993	6.48	6.40	1.2%	on time
1994	5.51	5.30	3.8%	5 day late
1995	4.51	4.50	0.2%	on time
1996	5.63	8.50	51.0%	1 day early
1997	6.41	6.00	6.4%	3 day late
1998	3.00	3.40	13.3%	3 day late
1999	4.57	5.20	13.7%	3 day late
2000	2.94	3.20	8.8%	2 day early
2001	3.53	6.20	75.4%	2 day early
2002	4.84	5.50	13.6%	2 day early
2003	6.29	6.79	8.0%	1 day early
2004	7.92	8.94	12.8%	2 day late
2005	7.92	9.17	15.8%	7 day late
2006	4.96	3.60	27.5%	9 day late
2007	5.44	4.65	14.6%	4 day late
2008	4.13	5.17	25.3%	4 day early
2009	4.29	9.11	112.5%	2 day early
2010 <sup>a</sup>	5.26	4.69	10.8%	1 day early
2011	8.60	11.56	34.4%	2 day late
2012	6.61	6.73	1.8%	1 day early
2013 <sup>b</sup>	_	_	_	_
2014	5.28	9.10	72.3%	1 day late
2015	6.30	5.89	6.5%	10 day late
2016	5.11	6.83	33.7%	2 day late
2017	4.61	7.11	54.2%	4 day late
			Average APE	Median APE
		All runs	24%	13%
		On time +	19%	13%
		All early	34%	19%

Total run was estimated by summing harvest and escapement throughout Upper Cook Inlet; in the Kenai and Kasilof rivers, escapements were converted to Bendix-equivalent units.

b Due to number of missed fishing days, the program was not used in 2013.

Table 6.-Projected total Kenai River sockeye salmon run (millions) in 2017 estimated from total southern OTF CPUE and age composition stock allocation.

Data t	hrough 24	July
